Before drawing up the insulin doses, gently roll all cloudy insulin preparations between the palms of the hands (or rotate the vial for at least one minute) to resuspend the insulin. Do not shake insulin vials; shaking causes the formation of bubbles, which take up space in the syringe and thereby alter the dose. If more than one type of insulin is required to manage the patient's diabetes, you can mix two different types of insulin in one syringe if they are compatible (Box 33-23), by following the steps demonstrated in Figure 33-20. When two types of insulin are mixed, the single injection minimizes the patient's discomfort that is associated with multiple injections. In hospitals, when you need to take capillary blood samples for blood glucose monitoring, always swab the patient's anticipated sample site (e.g., the fingertip) with an alcohol swab before taking the sample. Use of an aseptic technique prevents the introduction of microorganisms and protects patients from infection while in the hospital. Although diabetic patients are commonly educated not to use alcohol swabs in the home care setting, their use is essential to maintain asepsis and infection control standards in hospital settings. Always consult with agency protocol for special care required when treating diabetic patients.

► BOX 33-23 Procedural Guideline

Mixing Two Kinds of Insulin in One Syringe

Delegation Considerations:

The mixing of two kinds of insulin in one syringe cannot be delegated.

Equipment:

- Insulin vials
- Insulin syringe
- Alcohol swabs
- Medication administration report (MAR) or computer printout

Procedure:

1. Check the accuracy and completeness of each MAR or computer printout against the prescriber's original medication order. Check the patient's name and the medication name, dosage, route, and time for administration. Copy or rewrite any portion of the MAR that is difficult to read.
2. Carefully verify the insulin labels; compare the medication labels against the MAR before preparing the dose to ensure the correct type of insulin is prepared.
3. Perform hand hygiene.
4. If the insulin is cloudy, roll the bottle of insulin between your hands to resuspend the insulin preparation.
5. Wipe the tops of both insulin vials with the alcohol swabs.
6. Verify the insulin dosage against the MAR a second time.
7. If mixing rapid- or short-acting insulin with intermediate- or long-acting insulin, take the insulin syringe and aspirate a volume of air equivalent to the dose of insulin to be withdrawn from the intermediate- or long-acting insulin first. If two intermediate- or long-acting insulins are mixed, either vial can be prepared first.
8. Insert the needle and inject air into the vial of the intermediate- or long-acting insulin. Do not let the tip of the needle touch the insulin.
9. Remove the syringe from the vial of the intermediate- or long-acting insulin without aspirating the insulin.
10. With the same syringe, inject a volume of air that is equivalent to the dose of insulin to be withdrawn into the vial of the rapid- or short-acting insulin. Withdraw the correct dose into the syringe.
11. Remove the syringe from the rapid- or short-acting insulin vial after carefully removing air bubbles in the syringe to ensure the correct dose.
12. After verifying the insulin dosage with the MAR a third time, show the insulin preparation in the syringe to another nurse to verify the correct dose of insulin was prepared. Determine which point on the syringe scale represents the total of the combined units of insulin by adding the number of units of both insulins together (e.g., 3 units regular insulin + 10 units NPH insulin = 13 units total insulin).
13. Place the needle of the syringe back into the vial of the intermediate- or long-acting insulin. Be careful not to push the plunger, which would inject the insulin in the syringe into the vial.
14. Invert the vial, and carefully withdraw the desired amount of insulin into the syringe.
15. Withdraw the needle and check the fluid level in the syringe. Keep the needle of the prepared syringe sheathed or capped until you are ready to administer the medication. Show the syringe to another nurse to verify the correct dose was prepared.
16. Dispose of soiled medication supplies in the proper receptacle and perform hand hygiene.
17. Because rapid- or short-acting insulin binds with intermediate- or long-acting insulin, which reduces the action of the faster-acting insulin, administer the mixture within five minutes of preparing it.

Source: Adapted from the Canadian Diabetes Association. (n.d.). *Insulin: Things you should know*. Retrieved from <http://www.diabetes.ca/files/Insulin.pdf>; and American Diabetes Association. (2004). Insulin administration: Position statement. *Diabetes Care*, 27(15), S106–S109.

Administering Injections

Each injection route differs depending on the type of tissues the medication enters. The characteristics of the tissues influence the rate of medication absorption and thus the onset of medication action. Before injecting a medication, know the volume of the medication to administer, the medication's characteristics and viscosity, and the location of anatomical structures underlying the injection sites (Skill 33-5).

If you do not administer injections correctly, negative patient outcomes can result. Failure to select an injection site in relation to anatomical landmarks can result in nerve or bone damage during needle insertion. An inability to maintain stability of the needle and syringe unit can result in pain for the patient and possible tissue damage. If you fail to aspirate the syringe before injecting an intramuscular medication, the medication may accidentally be injected directly into an artery or vein. Injecting too large a volume of medication for the site selected causes the patient extreme pain and may result in local tissue damage.

Many patients, particularly children, fear injections. Patients with serious or chronic illness often are given several injections daily. You may be able to minimize the patient's discomfort in the following ways:

- Use a sharp-bevelled needle in the smallest suitable length and gauge.

- Position the patient as comfortably as possible, to reduce muscular tension.
- Select the proper injection site, by using anatomical landmarks.
- Divert the patient's attention from the injection by asking open-ended questions.
- Insert the needle quickly and smoothly to minimize tissue pulling.
- Hold the syringe steady while the needle remains in the tissues.
- Inject the medication slowly and steadily.

Subcutaneous Injections. Subcutaneous injections involve administering medications into the loose connective tissue under the dermis (see Skill 33-6, page 727). Because subcutaneous tissue is not as richly supplied with blood as the muscles, medication given by subcutaneous injection is absorbed more slowly than medication given by IM injections; however, medications injected subcutaneously are absorbed completely if the patient's circulatory status is normal. Because subcutaneous tissue contains pain receptors, the patient may experience some discomfort.

The best subcutaneous injection sites are the outer posterior aspect of the upper arms, the abdomen from below the costal margins to the iliac crests, and the anterior aspects of the thighs

Text continued on p. 730

► SKILL 33-5 Administering Injections

**Delegation Considerations**

The administration of injections cannot be delegated to an unregulated care provider (UCP). Instruct UCPs to report the occurrence of potential medication side effects or any changes in the patient's vital signs or level of consciousness (e.g., sedation) immediately.

Equipment

- Proper size syringe and needle:
- *Subcutaneous*: Syringe (1–3 mL) and needle (25–27 gauge, 1–1.6 cm)
- *Subcutaneous U-100 insulin*: Insulin syringe (0.3, 0.5, or 1 mL) with preattached needle (28–31 gauge)
- *IM*: Syringe 2–3 mL for adult, 0.5–1 mL for infants and small children
- Needle, with length corresponding to the site of injection and the age of the patient according to the following guidelines (Nicoll & Hesby, 2002):
- *Any site (children)*: 1.6–3.2 cm (depending on the size of the child)
- *Vastus lateralis (adults)*: 2.5–3.8 cm
- *Deltoid (adults)*: 2.5–3.8 cm
- *Ventrogluteal (adults)*: 3.8 cm
- *Intradermal and subcutaneous U-500 insulin*: 1 mL tuberculin syringe with preattached 26- or 27-gauge needle
- Small gauze pad, or alcohol swab, or both
- Vial or ampule of medication or skin test solution
- Clean gloves
- Medication administration record (MAR) or computer printout

Procedure**STEPS****For All Injections**

1. Check the accuracy and completeness of each MAR or computer printout against the prescriber's original medication order. Check the patient's name and the medication name, route, dosage, and time of administration. Copy or rewrite any portion of the MAR that is difficult to read.
2. Assess the patient's medical history, medication history, and history of allergies. Determine whether the patient is allergic to any substances and the normal allergic reaction experienced.
3. Check the date of expiration for the medication.
4. Observe the patient's verbal and nonverbal responses to receiving the injection.
5. Assess the patient for contraindications.
 - A. For subcutaneous injections:
Assess the patient for factors such as circulatory shock and reduced local tissue perfusion. Assess the adequacy of the patient's adipose tissue.
 - B. For intramuscular injections:
Assess the patient for muscle atrophy, reduced blood flow, and circulatory shock.

RATIONALE

- The order sheet is the most reliable source and only legal record of printout against the prescriber's original medication order. Check the MAR and the original medication order to ensure the patient receives the correct medications. Illegible MARs are a source of medication errors.
- Certain substances have similar compositions; never administer a substance to which a patient has a known allergy.
- Drug potency may increase or decrease when medications are expired.
- Injections can be painful. Some patients have anxiety, which can increase their experience of pain.
- Reduced tissue perfusion interferes with medication absorption and distribution. Physiological changes of aging and the patient's health may affect the amount of the patient's subcutaneous tissue. The amount of subcutaneous tissue influences the methods chosen for administering injections.
- Atrophied muscles absorb medication poorly. Factors that interfere with blood flow to muscles will impair the medication's absorption.

Critical Decision Point: Because of documented adverse effects to intramuscular injections, other routes of medication administration are safer. Verify that an intramuscular injection is necessary and explore alternative medication routes if possible (Nicoll & Hesby, 2002; World Health Organization [WHO], 2005).

6. Aseptically prepare the correct medication dose from an ampule or vial (see Skill 33-3). Ensure all air is expelled from the syringe. Check the label of medication against the MAR three times while preparing the medication. Create a removable label that shows the patient's name, the name of the drug, and the dosage. Apply the label to the removable needle cap.
 7. Take the medication to the patient at the right time and perform hand hygiene.
- Aseptic preparation ensures that the medication is sterile. Preparation techniques differ for ampules and vials. Checking the label against the MAR ensures the right medication is prepared for the right patient.
 - Taking the medication according to schedule ensures the patient receives the effect of the medication at the right time. Hand hygiene reduces the transfer of microorganisms.

► SKILL 33-5 Administering Injections—cont'd

8. Close the room curtain or door.
 9. Identify the patient using at least two patient identifiers. Compare the patient's name and one other identifier (e.g., the hospital identification number) on the MAR, computer printout, or computer screen against information on the patient's identification bracelet. Ask the patient to state his or her name if possible, for a third identifier.
 10. Compare the label on the medication with the MAR one more time at the patient's bedside.
 11. Describe the steps of procedure and inform the patient that the injection will cause a slight burning or stinging sensation.
 12. Perform hand hygiene; put on disposable gloves.
 13. Keep a sheet or gown draped over the patient's body parts that do not need to be exposed.
 14. Select an appropriate injection site. Inspect the skin surface over the injection site for bruises, inflammation, and edema.
 - A. *Subcutaneous injection*: Palpate the injection site for masses or tenderness. Avoid these areas. For patients who require daily insulin, rotate the injection site daily. Ensure the needle is the correct size by grasping a skin fold at the injection site with your thumb and forefinger. Measure across the skin fold. The needle should be one-half the distance across the fold to give it at a 90-degree angle.
 - B. *Intramuscular injection*: Note the integrity and size of the muscle and palpate for tenderness or hardness. Avoid these areas. If injections are given frequently, rotate the injection sites. Use the ventrogluteal site if possible.
 - C. *Intradermal injection*: Note any lesions or discolourations of the patient's forearm. Select an injection site three to four fingerwidths below the antecubital space and a handwidth above the wrist. If the forearm cannot be used, inspect the patient's upper back. If necessary, sites for subcutaneous injections may be used.
 15. Assist the patient to a comfortable position:
 - A. *Subcutaneous injection*: Have the patient relax the arm, leg, or abdomen, depending on the site chosen for injection.
 - B. *Intramuscular injection*: Position the patient depending on the site chosen (e.g., have the patient sit, lie flat, lie on one side, or lie prone).
 - C. *Intradermal injection*: Have the patient extend the elbow and support the elbow and forearm on a flat surface.
 - D. Speak with the patient about a subject of interest. Ask open-ended questions.
- Closing the curtain or door provides privacy and avoids distractions.
 - This process complies with the Joint Commission's (2007) requirements and improves medication safety. In most acute care settings, the name and identification number on the patient's armband and the MAR are used to identify patients. Identification bracelets are made at the time of the patient's admission and are the most reliable source of information. The patient's room number is *not* an acceptable identifier.
 - The final check of medication labels against the MAR at the patient's bedside reduces medication administration errors.
 - Describing the process to the patient helps to minimize the patient's anxiety.
 - Hand hygiene and the wearing of gloves reduces the transfer of microorganisms.
 - Use of a sheet or gown respects the dignity of the patient while only the area to be injected is exposed.
 - Injection sites should be free of abnormalities that may interfere with medication absorption. Injection sites that are used repeatedly can become hardened from lipohypertrophy (increased growth in fatty tissue). Do not inject an area that is bruised or shows signs associated with infection.
 - Subcutaneous injections can be inadvertently given in the muscle, especially when the injection site is in the abdomen or thigh (Annersten & Willman, 2005). Use of the appropriate size of needle ensures that medication will be injected in the subcutaneous tissue (Hunter, 2008; King, 2003).
 - Unless contraindications exist for this site, the ventrogluteal site is the preferred injection site for adults and children but for infants the vastus lateralis site should be used. (Cook & Murtagh, 2006; Hockenberry & Wilson, 2007; Nicoll & Hesby, 2002; Small, 2004).
 - An intradermal site should be free from lesions or discolourations so that results of skin test can be seen and interpreted correctly.
 - Relaxation of the injection site minimizes the patient's discomfort.
 - The position of the patient can reduce strain on the patient's muscle and minimize the discomfort of the injection.
 - The position of the patient stabilizes the injection site for easy accessibility.
 - Distraction reduces anxiety.
 - Injection into the correct anatomical site prevents injury to nerves, bones, and blood vessels.

Critical Decision Point: Ensure the patient's position is not contraindicated by a medical condition.

16. Relocate the injection site using anatomical landmarks.
- Injection into the correct anatomical site prevents injury to nerves, bones, and blood vessels.

Continued

► SKILL 33-5 Administering Injections—cont'd

video

17. Clean the injection site with an antiseptic swab. Touch the swab to the centre of the site and rotate outward in a circular direction for about 5 cm (see Step 17 illustration).
18. Hold the swab or gauze between the third and fourth fingers of your nondominant hand.
19. Remove the needle cap or sheath from the needle by pulling it straight off.
20. Hold the syringe between the thumb and forefinger of your dominant hand.
 - A. *Subcutaneous injection:* Hold the syringe as if you were holding a dart, palm down; or hold the syringe across the tops of your fingertips (see Step 20A illustration).

- The mechanical action of the swab removes secretions containing microorganisms.
- The gauze or swab is readily accessible when the needle is withdrawn.
- Preventing the needle from touching the sides of the cap avoids the risk of contamination.
- Quick, smooth injection requires proper manipulation of the syringe parts.

Step 17 Clean the injection site by using a circular motion.

Step 20A Hold the syringe as if grasping a dart.

- B. *Intramuscular injection:* Hold the syringe as if you were holding a dart, palm down.
- C. *Intradermal injection:* Hold the bevel of the needle pointing up.
21. Administer the injection:
 - A. *Subcutaneous injection*
 - (1) For an average-sized patient, spread the skin tightly across the injection site or pinch the skin with your nondominant hand.
 - (2) Inject the needle quickly and firmly at a 45- to 90-degree angle. Hold the skin fold until the needle has been withdrawn from the skin (Frid et al., 2010).
 - (3) For an obese patient, pinch the skin at the injection site and insert the needle at a 90-degree angle below the tissue fold.

- With the bevel pointing up, the medication is less likely to be deposited into tissues below dermis.
- The needle penetrates tight skin easier than loose skin. Pinching the skin elevates the subcutaneous tissue and may desensitize the area.
- Quick, firm insertion minimizes the patient's discomfort. (Injecting medication into compressed tissue irritates the nerve fibres.) Injecting at the correct angle prevents accidental injection into the muscle. Injecting into a raised skin fold is thought to result in a more diffuse depot of insulin, in contrast to a compact bolus injected without a pinch up (King, 2003).
- It is important to ensure that the injection is given in the subcutaneous adipose tissue rather than intradermally (just under the epidermis) or into the muscle (Hunter, 2008).

Critical Decision Point: Piercing a blood vessel during a subcutaneous injection is very rare, so aspiration is not necessary when administering subcutaneous injections.

► SKILL 33-5 Administering Injections—cont'd**video**

- (4) Inject the medication slowly (see Step 21A(4) illustration).

Step 21A (4) Inject the medication slowly.

B. Intramuscular injection

- (1) Position your nondominant hand at the proper anatomical landmarks and pull the skin down approximately 2.5–3.5 cm or laterally with the ulnar side of your hand to administer the injection in a Z-track. Hold this position until the medication is injected. Use your dominant hand to insert the needle quickly at a 90-degree angle into the muscle.
 - (2) If the patient's muscle mass is small, grasp a body of muscle between your thumb and fingers.
 - (3) After the needle pierces the skin, grasp the lower end of the syringe barrel with your nondominant hand to stabilize the syringe. Continue to hold the skin tightly with your nondominant hand. Move your dominant hand to the end of the plunger. Do not move the syringe.
 - (4) Pull back on the plunger. If no blood appears, inject the medicine slowly, at a rate of 1 mL per 10 seconds.
- The Z-track creates a zigzag path through the tissues to seal the needle track and avoid tracking of the medication. The Z-track should be used for all intramuscular injections (smaller needles may be needed for smaller muscles) (Beyea & Nicoll, 1995; Nicoll & Hesby, 2002).
 - Grasping the muscle ensures the medication reaches the muscle mass (Hockenberry & Wilson, 2007).
 - Smooth manipulation of the syringe reduces the patient's discomfort from needle movement. The skin must remain pulled until after the drug is injected to ensure Z-track administration.
 - Aspiration of blood into the syringe indicates intravenous placement of the needle. A slow injection rate reduces the chance of pain and tissue trauma (Nicoll & Hesby, 2002).

Critical Decision Point: If blood appears in the syringe, remove the needle and dispose of the medication and syringe properly. Prepare another dose of medication for injection.

- (5) Wait 10 seconds, and then smoothly and steadily withdraw the needle and release the skin. Apply gentle pressure with dry gauze if desired.
- A wait of 10 seconds allows time for the medication to absorb into the muscle before you remove the syringe and prevents the medication from leaking back out through the track created by the needle (Nicoll & Hesby, 2002).

C. Intradermal injection

- (1) With your nondominant hand, stretch the skin over the injection site with your forefinger or thumb.
 - (2) With the needle almost against the patient's skin, insert it slowly with the bevel pointed up at a 5- to 15-degree angle until resistance is felt. Advance the needle through the epidermis to approximately 3 mm below the skin surface. The needle tip can be seen through skin.
- The needle pierces tight skin more easily than loose skin.
 - This technique ensures the needle tip is in the dermis.

Continued

► SKILL 33-5 Administering Injections—cont'd

- (3) Inject the medication slowly. Normally, resistance is felt. If resistance is not felt, the needle is in too deep; remove and begin again. Your nondominant hand can stabilize the needle during the injection.
- (4) While injecting medication, notice that a small bleb of approximately 6 mm in diameter (resembling a mosquito bite) appears on the skin's surface (see Step 21C [4] illustration). Instruct the patient that this bleb is a normal finding.

Step 21C (4) The injection creates a small bleb.

22. Withdraw the needle while wiping an alcohol swab or gauze gently over the injection site.
 23. Apply gentle pressure. Do not massage the injection site. Put on a bandage if needed.
 24. Assist the patient to a comfortable position.
 25. Discard into a puncture- and leak-proof receptacle the uncapped needle or the needle enclosed in safety shield and attached to the syringe. Do *not* recap the needle.
 26. Remove disposable gloves and perform hand hygiene.
 27. Stay with the patient for 3–5 minutes to observe for any allergic reactions.
 28. Periodically return to the patient's room to ask whether the patient feels any acute pain, burning, numbness, or tingling at the injection site.
 29. Inspect the injection site, noting any bruising or induration.
 30. Observe the patient's response to medication at times that correlate with the medication's onset, peak, and duration.
 31. Ask the patient to explain the purpose and effects of the medication.
 32. For intradermal injections, use a skin pencil and draw a circle around the perimeter of the injection site. Read the site within an appropriate amount of time, which is determined by the type of medication or skin test administered.
- Slow injection minimizes the discomfort at the injection site. The dermal layer is tight and does not expand easily when the solution is injected. Stabilizing the needle prevents unnecessary movements and decreases the patient's discomfort.
 - The bleb indicates the medication is deposited in the dermis.
 - Support of tissue around the injection site minimizes the patient's discomfort during withdrawal of the needle. Dry gauze may minimize the patient's discomfort associated with the use of alcohol on nonintact skin.
 - Massage may cause underlying tissue damage. Massage of the intradermal site may disperse the medication into underlying tissue layers and thereby alter the test results.
 - Helping the patient to a comfortable position gives the patient a sense of well-being.
 - Proper needle disposal prevents injury to patients and health care personnel. Recapping the needle increases the risk of needle-stick injury (Health Canada, 1997).
 - Proper hygiene reduces the transmission of microorganisms.
 - Severe anaphylactic reaction is characterized by dyspnea, wheezing, and circulatory collapse and is a life-threatening emergency.
 - Continued discomfort may indicate injury to underlying bones or nerves.
 - Bruising or induration indicates a complication associated with the injection. Document your findings and notify the patient's health care provider. Provide a warm compress to the site.
 - Intramuscular medications are rapidly absorbed. Adverse effects of parenteral medications may develop rapidly. Your observations evaluate the efficacy of the medication action.
 - Questioning the patient will help to evaluate the patient's understanding of the information you have taught.
 - The pencil mark makes the injection site easy to find. Results of skin testing are read at various times, on the basis of the type of medication used or the type of skin test completed. Refer to the manufacturer's directions to determine when to read the test's results.

Unexpected Outcomes

Raised, reddened, or hard zone (induration) around intradermal test site

Related Interventions

- Notify the patient's health care provider.
- Document the patient's sensitivity to the injected allergen or the positive test if tuberculin skin testing was completed.

► SKILL 33-5 Administering Injections—cont'd

Hypertrophy of skin, resulting from repeated subcutaneous injections

Signs and symptoms of allergy or side effects

Complaints of localized pain, numbness, tingling, or burning sensation at injection site, indicating possible injury to nerve or tissues

- Do not use this site for future injections.
- Instruct patient not to use the injection site for 6 months.
- Follow the institutional policy or guidelines for the appropriate response to adverse drug reactions.
- Notify the patient's health care provider immediately.
- Add allergy information to the patient's medical record.
- Assess the injection site.
- Document your findings.
- Notify the patient's health care provider.

Recording and Reporting

- Chart the medication dose, route, site, time, and date of injection on the MAR immediately after giving medication, as per agency policy.
- Document if the scheduled medication is withheld and record the reason as per agency policy.
- Report any undesirable effects from the medication to the prescriber.
- Record the patient's response to medications in the nurses' notes and report to prescriber if required.

Home Care Considerations

- Assess the patient's readiness to learn before instructing him or her on how to administer self-injections. Some patients are hesitant to administer injections to themselves; relieve any anxiety before teaching this skill to a patient.
- Patients can often purchase or obtain sharps boxes for home use. If this purchase is not feasible, a hard plastic bottle that is nontransparent (e.g., a fabric softener bottle or a detergent bottle) may be used to safely store syringes after use. Disposal of needles used in the home varies among communities. Check with local authorities to verify how to appropriately dispose of needles.

► SKILL 33-6 Adding Medications to Intravenous Fluid Containers**Delegation Considerations**

Adding medications to IV fluid containers cannot be delegated to unregulated care providers (UCPs). (In some institutions, the pharmacist may add medications to the primary containers of IV solutions to promote safe medication administration and ensure asepsis.)

Equipment

- Vial or ampule of prescribed medication
- Syringe of appropriate size (5–20 mL)
- Sterile needle (2.5–3.8 cm, 19–21 gauge) with special filters (if required)
- Diluent as indicated (e.g., sterile water, normal saline)
- Sterile IV fluid container (bag or bottle, 25–1000 mL in volume)
- Alcohol or antiseptic swab
- Label to attach to IV bag or bottle
- Medication administration record (MAR) or computer printout

Procedure**STEPS****RATIONALE**

1. Check the accuracy and completeness of each MAR or computer printout against the prescriber's original medication order. Check the patient's name and the medication name, route, dosage, and time of administration. Copy or rewrite any portion of the MAR that is difficult to read.
2. Assess the patient's medical history.
3. Collect information necessary to administer the drug safely, including the medication's action, purpose, side effects, normal dose, time of peak onset, and nursing implications.
4. When more than one medication is to be added to the IV solution, assess for compatibility of the medications.
5. Assess the patient's systemic fluid balance, as evidenced by skin hydration and turgor, body weight, pulse, blood pressure, and ratio of fluid intake to urinary output.
6. Assess the patient's history of medication allergies.
7. Perform hand hygiene.
8. Assess the IV insertion site for signs of infiltration or phlebitis (see Chapter 39).

- Medications often are incompatible when mixed together. Chemical reactions that occur result in clouding or crystallization of IV fluids. Check the hospital policy for a list of approved medication compatibilities.
- Continuous IV infusions can lead to fluids that infuse too rapidly, thereby causing circulatory overload, especially in children and older adults (Ebersole et al., 2004; Hockenberry & Wilson, 2007).
- The IV administration of medications causes rapid effects. Allergic response can be immediate.
- An intact, properly functioning site ensures medication is given safely.

Continued

► SKILL 33-6 Adding Medications to Intravenous Fluid Containers—cont'd

9. Assess the patient's understanding of the purpose of the medication therapy.
 10. Prepare the prescribed medication (see Skill 33-4); use aseptic techniques. Ensure that you compare the label of the medication with the MAR two times while preparing the medication.
 11. Perform hand hygiene.
 12. Compare the labels of the medication and the IV fluid bag with the MAR or computer printout.
 13. Add the medication to a new container (usually in the medication room or at medication cart):
 - A. *Solution in a bag:* Locate the medication injection port on the plastic IV solution bag. The port has a small rubber stopper at the end. Do not select the port for the IV tubing insertion or the air vent.
 - B. *Solution in a bottle:* Locate the injection site on the IV solution bottle, which is often covered by a metal or plastic cap.
 - C. Wipe the port or injection site with alcohol or an antiseptic swab (see Step 13C illustration).
 - D. Remove the needle cap or sheath from the syringe and insert the needle of the syringe or the needleless device through the centre of injection port or site; inject the medication (see Step 13D illustration).
- Proper technique ensures the medication is sterile; preparation techniques differ for ampules and vials.
 - Checking the labels ensures the correct medication is injected into the correct IV fluid.
 - The medication injection port is self-sealing to prevent introduction of microorganisms after repeated use.
 - Accidental injection of medication through the main tubing port or the air vent can alter the pressure within the bottle and cause fluid leaks through the air vent. The cap seals the bottle to maintain its sterility.
 - Cleaning the port of injection site reduces the risk of introducing bacteria into the port.
 - Injection of the needle into the sides of the port may cause a leak and lead to fluid contamination.

Step 13C Clean the injection port with an antiseptic swab.

Step 13D Inject the medication through the port.

- E. Withdraw the syringe from the bag or bottle.
 - F. Mix the medication and the IV solution by holding the bag or bottle and turning it gently end to end.
 - G. Complete the medication label by printing the name and dose of the medication, the date and time of administration, and your initials. Apply the label to the bottle or bag, being careful not to cover any essential information preprinted on the bottle or bag. Spike the bag or bottle with the IV tubing.
14. Take the assembled items to the patient's bedside at the right time.
- When the syringe is withdrawn, the injection port self-seals to prevent the introduction of microorganisms.
 - Gently turning the bag or bottle allows even distribution of the medication.
 - The label informs other health care providers of the contents of the bag or bottle.
 - Concealing important information on the IV bag can lead to medication errors.

SKILL 33-6 Adding Medications to Intravenous Fluid Containers—cont'd

15. Identify the patient using at least two patient identifiers. Compare the patient's name and one other identifier (e.g., the hospital identification number) on the MAR, computer printout, or computer screen against information on the patient's identification bracelet. Ask the patient to state his or her name if possible, for a third identifier.

16. Prepare the patient by explaining that the medication is to be given through the existing IV line or a new line that will be started. Explain that no discomfort should be felt during the medication infusion. Encourage the patient to report symptoms of discomfort.

17. Connect the infusion tubing or spike container to the existing tubing. Regulate the infusion at the ordered rate.

- Most IV medications do not cause discomfort when diluted; however, potassium chloride is irritating. Pain at the insertion site may be an early indication of infiltration.

- Properly regulated infusion prevents rapid infusion of fluid.

Critical Decision Point: Some medications (e.g., potassium chloride) can cause serious adverse reactions, including fatal cardiac dysrhythmias. These medications should be infused on an IV pump. Check the institutional guidelines or policies indicating which IV medications require administration on an IV pump.

18. Add the medication to the existing container.

Critical Decision Point: Because you cannot know exactly how much IV fluid remains in an existing hanging IV container, you are unable to determine the exact concentration of the medication in the IV solution. Therefore, it is recommended that medications be added to new IV fluid containers whenever possible.

A. Prepare a vented IV bottle or plastic bag:

(1) Check the volume of the solution remaining in the bottle or bag.

(2) Close off the IV infusion clamp.

(3) Wipe the medication port with an alcohol or antiseptic swab.

(4) Remove the needle cap or sheath from the syringe; insert the syringe needle or needleless device through the injection port and inject the medication.

(5) Withdraw the syringe from the bag or bottle.

(6) Lower the bag or bottle from the IV pole and gently mix the medication and the IV solution by holding the bag or bottle and turning it gently end to end. Rehang the bag or bottle.

B. Complete the medication label and apply it to the unprinted side of the IV solution bag or bottle. Do not cover the imprinted label of the solution.

C. Regulate the infusion to the desired rate. Use an IV pump if indicated.

19. Properly dispose of equipment and supplies. Do not recap the needle or syringe. Discard the specially sheathed needles as a unit with the needle covered.

20. Perform hand hygiene.

21. Observe the patient for signs or symptoms of medication reaction.

22. Observe the patient for signs and symptoms of fluid volume excess.

23. Periodically return to the patient's room to assess the IV insertion site and the rate of infusion.

24. Observe the patient for signs or symptoms of IV infiltration.

25. Ensure that a label is applied to the IV tubing; the label must state the date and time that the IV tubing was opened and must be attached to the IV infusion system. Consult with agency policy regarding frequency of changing the IV tubing.

- Proper minimal volume (see drug insert) is needed to dilute the medication adequately.

- Closing the clamp prevents medication from directly entering the patient's circulation system when it is injected into the bag or bottle.

- Cleaning the port mechanically removes microorganisms that could enter container during needle insertion.

- The injection port is self-sealing and prevents fluid leaks.

- Gently turning the bag or bottle ensures the medication is evenly distributed.

- The label informs other health care providers of the contents of the bag or bottle. Concealing important information on the IV bag can lead to medication errors.

- Proper regulated infusion prevents rapid infusion of fluid.

- Proper disposal of the needle prevents injury to both you and the patient. Capping of needles increases risk of needle-stick injuries.

- IV medications can cause rapid effects.

- Rapid uncontrolled infusion can cause circulatory overload.

- Over time, the IV site may become infiltrated or the needle may become malpositioned. The flow rate may change according to patient's body position or the volume of solution left in the container.

- Infiltrated medications can injure tissue.

- Most agencies have policies indicating that IV tubing should be changed every 72 hours. The frequency of changing IV tubing may increase on the basis of the solution being administered (e.g., antibiotics, or total parental nutrition [TPN]) or the type of in-dwelling IV catheter (e.g., central line). Changing the IV tubing helps to prevent nosocomial infections.

► SKILL 33-6 Adding Medications to Intravenous Fluid Containers—cont'd

26. Assess the IV tubing frequently for integrity and occlusions.

27. Ask the patient to explain the purpose and effects of the medication therapy.

- Disruptions in the integrity of the IV tubing can lead to the patient not receiving the required IV therapy or medication and may lead to infection.

Unexpected Outcomes

Adverse or allergic reaction to medication

Signs of fluid volume overload (e.g., abnormal breath sounds, shortness of breath, intake greater than output)

Swelling, warmth, redness, and tenderness at intravenous site, indicating phlebitis (see Chapter 39)

Coolness, pallor, and swelling at intravenous site, indicating infiltration (see Chapter 39)

Related Interventions

- Follow institutional policy or guidelines for your appropriate response to and reporting of adverse drug reactions.
- Notify the patient's health care provider immediately.
- Add the allergy information to the patient's medical record.
- Assess the patient for compromised circulatory regulation (vital signs, input:output, focused respiratory and cardiac assessments).
- Stop the IV infusion.
- Notify the patient's health care provider immediately.
- Stop IV infusion and discontinue IV.
- Treat the IV site as indicated by institutional policy.
- If continuation of IV therapy is indicated, insert a new IV site.
- Some IV medications are extremely harmful to the subcutaneous tissue.
- Provide IV extravasation care as indicated by institutional policy, or use a medication reference manual or consult a pharmacist to determine the appropriate follow-up care.

Recording and Reporting

- Record the solution and medication added to parenteral fluid on the appropriate form.
- Report any adverse effects to the patient's health care provider, and document adverse effects according to institutional policy.

(Figure 33-21). The site most frequently recommended for heparin injections is the abdomen (Figure 33-22). Other recommended sites are the scapular areas of the upper back and the upper ventral or dorsal gluteal areas. The injection site chosen should be free of skin lesions, bony prominences, and large underlying muscles or nerves.

The administration of low-molecular-weight heparin (LMWH) (e.g., enoxaparin) requires special considerations. The injection site is the right or left side of the abdomen at least 5 cm from the umbilicus. Administer LMWH in its prefilled syringe with the attached needle; do not expel the air bubble in the syringe before giving the medication. The needle should be introduced into a skin fold held between the thumb and forefinger; the skin fold should be held throughout the injection. To minimize bruising, do not rub the injection site after injection (Sanofi-Aventis, 2006).

When giving U-100 insulin, use U-100 insulin syringes with preattached 26- to 31-gauge needles; when giving U-500 insulin, use 1 mL tuberculin syringes (Institute for Safe Medication Practices, 2002). Recommended sites for insulin injections include the upper arm and the anterior and lateral portions of the thigh, buttocks, and abdomen. Patients with diabetes who inject insulin should practise intrasite rotation (rotating injection sites within the same body part) to provide greater consistency in the absorption of insulin. For example, if the morning insulin is injected into the patient's arm, then a subsequent injection should also be given in the arm but at least 2.5 cm away from the previous site. No injection site should be used again for at least one month. The rate of insulin absorption varies depending on the site: the abdomen has

Figure 33-21 Sites recommended for subcutaneous injections.

the quickest absorption, followed by the arms, thighs, and buttocks (American Diabetes Association, 2004; Canadian Diabetes Association, 2008). For subcutaneous injections of insulin, pinch the skin and insert the needle at a 90-degree angle; inject the insulin, then release the pinched skin, count five to six seconds and remove the needle.

Only small doses (0.5 to 1 mL) of water-soluble medications should be given subcutaneously because the tissue is sensitive to irritating solutions and large volumes of medications. Medications can collect within the tissues to cause sterile abscesses, which appear as hardened, painful lumps under the skin.

A patient's body weight indicates the depth of the subcutaneous layer. Therefore, choose the needle length and angle of insertion based on the patient's weight and an estimation of the amount of subcutaneous tissue (Annersten & Willman, 2005). In general, medications can be injected in the subcutaneous tissue of a normal-sized patient using a 25-gauge 1.6 cm needle inserted at a 45-degree angle (Figure 33-23) or a 1.3 cm needle inserted at a 90-degree angle. A child may require only a 1.3 cm needle. If the patient is obese, pinch the tissue and use

a needle long enough to insert through the fatty tissue at the base of the skinfold. The preferred needle length is one-half the width of the skinfold; the angle of insertion may be between 45 and 90 degrees. Thin patients may have insufficient tissue for subcutaneous injections; the upper abdomen is the best injection site for these patients. To ensure a subcutaneous medication reaches the subcutaneous tissue, follow this rule: if you can grasp 5 cm of tissue, insert the needle at a 90-degree angle; if you can grasp 2.5 cm of tissue, insert the needle at a 45-degree angle (Rushing, 2004).

Intramuscular Injections. The intramuscular (IM) route provides faster medication absorption than the subcutaneous route because of a muscle's greater vascularity; however, intramuscular injections are associated with many risks. Therefore, when administering a medication by the intramuscular route, you must first verify that the injection is justified (Nicoll & Hesby, 2002; WHO, 2005). In many cases, such as influenza and pneumonia vaccinations, no alternative routes exist to administer the medication.

Use a longer and heavier-gauge needle to pass through the subcutaneous tissue and penetrate the deep muscle tissue (see Skill 33-5). The patient's body weight and the amount of adipose tissue can influence the selection of a needle size. For example, an obese patient may require a needle 7.5 cm long, whereas a thin patient may require a 1.3 to 2.5 cm needle.

The angle of insertion for an intramuscular injection is 90 degrees (see Figure 33-23). Muscle is less sensitive to irritating and viscous medications. A normal, well-developed patient can tolerate 3 mL of medication into a larger muscle without severe muscle discomfort. A larger volume of medication is unlikely to be absorbed properly. Children, older adults, and thin patients can tolerate only 2 mL of an intramuscular injection. Do not give more than 1 mL to small children and older infants, and do not give more than 0.5 mL to smaller infants (Hockenberry & Wilson, 2007).

Assess the muscle integrity of the selected site before giving an injection. The muscle should be free of tenderness. Repeated injections in the same muscle can cause severe discomfort. Ensure that the patient is relaxed, then palpate the muscle to rule out any hardened lesions. You can minimize discomfort during an injection by helping the patient to assume a position that will help reduce muscle strain. Other interventions, such as distraction and applying pressure to the intramuscular site,

Figure 33-22 Giving subcutaneous heparin in the abdomen.

Figure 33-23 Comparison of angles of insertion for intramuscular (90 degrees), subcutaneous (45 and 90 degrees), and intradermal (15 degrees) injections.

BOX 33-24

Characteristics of Intramuscular Sites and Indications for Usage

Vastus Lateralis Muscle

- Lacks major nerves and blood vessels
- Facilitates rapid drug absorption
- Used frequently with infants (younger than 12 months old) receiving immunizations
- May also be used in older children and toddlers receiving immunizations

Ventrogluteal Muscle

- Offers a deep site, situated away from major nerves and blood vessels
- Offers less chance of contamination in incontinent patients and infants
- Identified easily by prominent bony landmarks
- Is preferred site for medications (e.g., antibiotics) that are larger in volume, more viscous, and irritating for adults, children, and infants

Deltoid Muscle

- Is easily accessible but the muscle is not well developed in most patients
- May be used for small amounts of medications
- Not used in infants or children with underdeveloped muscles
- Use of the muscle involves potential for injury to the brachial artery and to the radial and ulnar nerves
- May be used for immunizations of toddlers, older children, and adults
- Recommended site for hepatitis B vaccine and rabies injections

may be used to decrease pain during an intramuscular injection.

Sites. When selecting an intramuscular site, consider the following: Is the area free of infection or necrosis? Do local areas show signs of bruising or abrasions? Where is the location of underlying bones, nerves, and major blood vessels? What volume of medication is to be administered? Each site has certain advantages and disadvantages. The characteristics of each intramuscular site and the indications for use of each site are listed in Box 33-24.

safety alert Researchers who have investigated complications associated with intramuscular injection sites indicate that the ventrogluteal site is the preferred site for most injections administered to adults and children, including infants of any age (Cook & Murtagh, 2006; Hockenberry & Wilson, 2007; Nicoll & Hesby, 2002).

Locate the ventrogluteal muscle by placing the heel of your hand over the greater trochanter of the patient's hip with the wrist perpendicular to the femur. Use your right hand for the left hip, and your left hand for the right hip. Point your thumb toward the patient's groin and point your fingers toward the patient's head; point your index finger to the anterior superior iliac spine, and extend your middle finger back along the iliac crest toward the buttocks. The index finger, the middle finger, and the iliac crest form a V-shaped triangle; the injection site is the centre of the triangle (Figure 33-24). The patient may lie on his or her side or back. Flexing of the knee and hip helps the patient to relax this muscle.

Figure 33-24 A, Landmarks for the ventrogluteal site. B, Giving IM injection in the ventrogluteal muscle.

Ventrogluteal Muscle. The ventrogluteal muscle, which involves the gluteus medius, is situated deep and away from major nerves and blood vessels. It is a safe site for all patients because it is a large muscle that is well developed in adults and young children, including those who do not walk (Nicoll & Hesby, 2002). Research shows that injuries such as fibrosis, nerve damage, abscess, tissue necrosis, muscle contraction, gangrene, and pain have been associated with all of the common intramuscular sites except the ventrogluteal site (Beyea & Nicoll, 1995). The only published case study of a complication at the ventrogluteal site when done correctly reported a local reaction to the medication, which is not a complication associated with the site itself (Nicoll & Hesby, 2002).

Vastus Lateralis Muscle. This thick and well-developed muscle is located on the anterior lateral aspect of the thigh and extends in an adult from a handbreadth above the knee to a handbreadth below the greater trochanter of the femur (Figure 33-25). Use the middle third of the muscle for injection. The width of the muscle usually extends from the midline of the thigh to the midline of the thigh's outer side. When administering injections to young children or cachectic patients, grasp the body of the muscle during injection to ensure the medication is deposited in the muscle tissue. To help relax the muscle, ask the patient to assume a sitting position or to lie flat with leg extended. The vastus lateralis site is often used when infants, toddlers, and children are administered biologicals (e.g., immune globulins, vaccines, or toxoids) (Nicholl & Hesby, 2002).

Dorsogluteal Muscle. In the past, the dorsogluteal muscle has been a traditional site for intramuscular injections. However,

Figure 33-25 A, Landmarks for the vastus lateralis site. B, Giving IM injection in the vastus lateralis muscle.

the exact location of the sciatic nerve varies from one person to another. If a needle hits the sciatic nerve, the patient may experience permanent or partial paralysis of the involved leg. Therefore, do *not* use the dorsogluteal site (Cook & Murtagh, 2006; Nicoll & Hesby, 2002; Small, 2004).

Deltoid Muscle. Although the deltoid site is easily accessible, the muscle is not well developed in many patients. A potential for injury exists when using this site because the axillary, radial, brachial, and ulnar nerves and the brachial artery lie within the upper arm along the humerus (Figure 33-26, A). Use this site only for small medication volumes, when giving immunizations, or when other sites are inaccessible because of dressings or casts (Nicoll & Hesby, 2002).

To locate the deltoid muscle, fully expose the patient's upper arm and shoulder. Do not roll up a tight-fitting sleeve. Have the patient relax the arm at the side and flex the elbow. The patient may sit, stand, or lie down (Figure 33-26, B). Palpate the lower edge of the acromion process, which forms the base of a triangle in line with the midpoint of the lateral aspect of the upper arm. The injection site is in the centre of the triangle, approximately 3 to 5 cm below the acromion process (Nicoll & Hesby, 2002). You may also locate the site by placing four fingers across the deltoid muscle, with your top finger along the acromion process. The injection site is then three fingerwidths below the acromion process.

Technique for Intramuscular Injections. When administering IM injections, the **Z-track method** is recommended because it minimizes local skin irritation by sealing the medication in the muscle tissue. Insert a new needle into the syringe after preparing the medication so that no solution remains on the outside of the needle shaft. For the Z-track technique, select an intramuscular site, preferably in a large, deep muscle, such

Figure 33-26 A, Landmarks for the deltoid site. B, Giving IM injection in the deltoid muscle.

as the ventrogluteal muscle; smaller needles may need to be used for smaller muscles (Nicoll & Hesby, 2002). After preparing the site with an antiseptic swab, pull the overlying skin and subcutaneous tissues approximately 2.5 to 3.5 cm laterally to the side. Holding the skin taut with your nondominant hand, insert the needle deep into the muscle, and slowly inject the medication if no blood return is observed on aspiration. The needle remains inserted for 10 seconds to allow the medication to disperse evenly rather than channelling back up the track of the needle. Then, withdraw the needle and release the skin. This technique leaves a zigzag path that seals the needle track where the tissue planes slide across each other (Figure 33-27). The medication cannot escape from the muscle tissue. Injections using this technique cause less discomfort and fewer lesions at the injection site (Nicoll & Hesby, 2002).

Intradermal Injections. Intradermal injections are commonly performed for skin testing (e.g., tuberculin screening and allergy tests). Because these medications are potent, they are injected into the dermis, where blood supply is reduced and medication absorption occurs slowly. If the medications enter the circulation too rapidly, a patient may have a severe anaphylactic reaction.

For accurate skin testing, you must be able to see the injection site clearly to detect changes in colour and tissue integrity. Intradermal sites should be lightly pigmented, free of lesions, and relatively hairless. The inner forearm and upper back are ideal locations.

Use a tuberculin or small hypodermic syringe for skin testing. The angle of insertion for an intradermal injection is 5 to 15 degrees (see Figure 33-23), with the bevel of the needle pointed up. As you inject the medication, a small bleb resembling a mosquito bite should appear on the skin's surface (see Skill 33-5). If a bleb does not appear or if the site bleeds after you withdraw the needle, the medication may have entered the subcutaneous tissues. In this case, the test results will not be valid.

Safety in Administering Medications by Injection

Needleless Devices. Needle-stick injuries occur frequently in all health care settings. Some hospitals report that one-third of nursing staff suffer needle-stick injuries each year (Canadian Centre for Occupational Health and Safety [CCOHS], 2005). However, because many workers do not report their injuries, the incidence of needle-stick injuries is probably

higher. Needle-stick injuries commonly occur when needles are recapped, IV lines and needles are mishandled, or needles are left at a patient's bedside. The risk of exposure of health care workers to bloodborne pathogens has led to the development of "needleless devices" or special needle safety devices.

Special syringes are designed with a sheath or guard that covers the needle after it is withdrawn from the skin (Figure 33-28). The needle is immediately covered to eliminate the

Figure 33-27 A, Pulling on the overlying skin during IM injection moves tissue to prevent later tracking. B, The Z-track left after injection prevents the deposit of medication through sensitive tissue.

Figure 33-28 Needle with plastic guard to prevent needle sticks. A, Position of guard before injection. B, After injection, the guard locks in place, covering the needle.

Figure 33-29 Sharps disposal using only one hand.

possibility of a needle-stick injury. The syringe and sheath are disposed of together in a receptacle. Needleless devices should be used whenever possible to reduce the risk of injury from needle sticks and sharps (CCOHS, 2005; Health Canada, 1997, 1999; Wilburn & Eijkemans, 2004).

Needles and other instruments that are considered “sharps” are always disposed of into clearly marked containers that are puncture-proof and leak-proof (Figure 33-29). A needle should never be forced into a needle disposable receptacle that is full. Never place used needles and syringes in a wastebasket, in your pocket, on a patient’s meal tray, or at the patient’s bedside. Box 33-25 summarizes recommendations for the prevention of needle-stick injuries.

Intravenous Administration. Medications are administered intravenously by the following methods:

1. As mixtures within large volumes of intravenous fluids
2. By injection of a bolus, or small volume, of medication through an existing intravenous infusion line or intermittent venous access (heparin or saline lock)
3. By “piggyback” infusion of a solution containing the prescribed medication and a small volume of intravenous fluid through an existing intravenous line

In all three methods, the patient has either an existing intravenous infusion line or an intravenous access site (sometime called a heparin or saline lock). In most institutions, policies and procedures list the persons who may give intravenous medications and the situations in which these medications may be given. These policies are based on the medication, capability, and availability of staff, and the type of monitoring equipment available.

Chapter 39 describes the technique for performing venipuncture and establishing continuous intravenous fluid infusions. Medication administration is only one reason for supplying intravenous fluids. Intravenous fluid therapy is used primarily for fluid replacement in patients unable to take

► BOX 33-25 Recommendations for the Prevention of Needle-Stick Injuries

- Avoid using needles when effective needleless systems or sharps with engineered sharps injury protections (SESIP) safety devices are available.
- Never recap needles.
- Never move an exposed needle tip toward an unprotected hand.
- Plan safe handling and safe disposal of needles before beginning the procedure.
- Immediately dispose of needles, needleless systems, and SESIP into puncture-proof disposal containers located near the area of use.
- Maintain occupational health and safety standards that include the following:
 - Assessment and implementation of innovations in procedures and technological developments to reduce risks of exposure to contaminated sharps
 - Employee training to address the risks, hazards, and recommended precautions, and the importance of hepatitis B vaccination where appropriate
 - Documentation of consideration and use of appropriate, commercially available, and effective safer devices
 - Selection of devices that do not jeopardize patient or employee safety and are determined to be medically advisable
 - Documentation of input from employees regarding methods to reduce exposure
 - Annual re-examination of occupational health and safety standards
- Maintain a needle-stick injury reporting protocol that protects the privacy of persons who have had sharps injuries and includes the following information:
 - Type and brand of device involved in the incident
 - Location of the incident (e.g., name of the department or work area)
 - Description of the incident
 - Protection of privacy for both the employee and patient involved in the needle-stick injury

oral fluids and as a means of supplying the patient with electrolytes and nutrients.

When using any method of intravenous medication administration, observe patients closely for symptoms of adverse reactions. After a medication enters the bloodstream, it begins to act immediately, and its action cannot be stopped. Thus, take special care to avoid errors in dose calculation and preparation. Carefully follow the 10 rights of safe medication administration, double-check your medication calculations with another nurse, and know the desired action and side effects of every medication that you administer. If the medication has an antidote, it must be available during administration. When administering potent medications, assess the patient’s vital signs before, during, and after infusion.

Administering medications by the intravenous route has advantages. Use the intravenous route in emergencies when a fast-acting medication must be delivered quickly. The intravenous route is also preferred when constant therapeutic blood levels need to be established. Some medications are highly alkaline and irritating to the muscle and subcutaneous tissue. These medications cause less discomfort when given intravenously.

safety alert Because IV medications are immediately available to the bloodstream after they are administered, verify the prescribed rate of administration with a drug reference manual or a pharmacist before giving any IV medication. This step ensures the medication is administered safely over the appropriate amount of time. Patients can experience severe adverse reactions if IV medications are administered too quickly.

Large-Volume Infusions. Of the three methods of administering intravenous medications, mixing medications in large volumes of fluids is the safest and easiest. Medications are diluted in large volumes (500 mL or 1000 mL) of compatible IV fluids, such as normal saline or lactated Ringer's solution (Skill 33-6). In most institutions, the pharmacist adds medications to the primary container of IV solution to ensure asepsis and to reduce the possibility of medication errors. Because the medication is not in a concentrated form, the risk of side effects or fatal reactions is minimal when infused over the prescribed time frame. Vitamins and potassium chloride are two types of medications commonly added to intravenous fluids. However, continuous infusion presents risks: if the intravenous fluid is infused too rapidly, the patient may suffer circulatory fluid overload.

Intravenous Bolus. An intravenous bolus, or "push," involves the introduction of a concentrated dose of a medication directly into the patient's systemic circulation (Skill 33-7). A bolus has the advantage of requiring only a small amount of fluid to deliver the medication; therefore, the bolus is useful when the patient is on restricted fluids. However, an intravenous bolus, or "push," is the most dangerous method for administering medications because you have no time to correct an error. Also, a bolus may cause direct irritation to the lining of the blood vessels. Before administering a bolus, confirm the placement of the IV line by obtaining a blood return through the intravenous catheter or needle. The inability to obtain a blood return suggests that the needle or catheter is in the patient's tissues or is resting against the vein wall. Never give a medication intravenously if the insertion site appears puffy or edematous or if the intravenous fluid cannot flow at the proper rate. Accidental injection of a medication into the tissues around a vein can cause pain, sloughing of tissues, and abscesses, depending on the medication's composition.

Determine the rate of administration of an intravenous bolus medication by the amount of medication that can be given per minute. For example, if a patient is to receive 4 mL of a medication over 2 minutes, give 2 mL of the intravenous bolus medication every minute. Research each medication to determine the recommended concentration and rate of administration. When delivering a medication intravenous push, consider the purpose for which a medication is prescribed and any potential adverse effects related to the rate or route of administration.

Volume-Controlled Infusions. IV medications can also be administered through small amounts (50 to 100 mL) of

compatible IV fluids. The fluid is within a secondary fluid container separate from the primary fluid bag. The container connects directly to the primary IV line or to separate tubing that inserts into the primary line. Three types of containers are volume-control administration sets (e.g., Volutrol or Pediatrol): piggyback sets, tandem sets, and mini-infusors. The use of volume-controlled infusions has several advantages:

- The risk of rapid-dose infusion by IV push is reduced. Medications are diluted and infused over longer time intervals (e.g., 30 to 60 minutes).
- Medications that are stable for only a limited time in solution (e.g., antibiotics) can be administered.
- IV fluid intake can be controlled.

Volume-Control Administration. Volume-control administration (e.g., Volutrol, Buretrol, Pediatrol) sets are small (50 to 150 mL) containers that attach just below the primary infusion bag or bottle. The set is attached and filled in a manner similar to the procedure used with a regular intravenous infusion; however, the priming or filling of the set is different and depends on the type of filter (floating valve or membrane). A Buretrol or Volutrol is used to deliver IV fluids in a safe manner to children in many agencies even when infusion pumps are used. Follow package directions for priming sets (see Chapter 39).

Piggyback. A piggyback is a small (25 to 250 mL) IV bag or bottle that connects to short tubing lines that, in turn, connect to the upper Y-port of a primary infusion line or to an intermittent venous access (Figure 33-30). The piggyback tubing is a microdrip or macrodrip system (see Chapter 39). The set is called a piggyback because the small bag or bottle is set higher than the primary infusion bag or bottle. In the piggyback

► SKILL 33-7 Administering Medications by Intravenous Bolus

Delegation Considerations

The administration of medications by IV bolus cannot be delegated to unregulated care providers (UCPs). Instruct UCPs to report immediately any unexpected drug reactions, discomfort at the infusion site, and changes in any required vital signs.

Equipment

- A watch with a second hand
- Medication administration record (MAR) or computer printout
- Clean gloves
- Antiseptic swab
- IV push (existing line):
 - Medication in a vial or ampule
 - Syringe for medication preparation
 - Needleless device or sterile needle (21–25 gauge)
- IV lock:
 - Syringe and needleless device (21–25 gauge) for medication preparation
 - Vial of the appropriate flush solution (saline is most common, but heparin may also be used; if heparin is used, the most common concentration is 10 to 100 units; check agency policy)

Procedure

STEPS

RATIONALE

1. Check the accuracy and completeness of each MAR or computer printout against the prescriber's original medication order. Check the patient's name and the medication name, route, dosage, and time of administration. Copy or rewrite any portion of the MAR that is difficult to read.

Critical Decision Point: Some IV medications can be pushed safely only when the patient is being continuously monitored for dysrhythmias, blood pressure changes, or other adverse effects. Therefore, some medications can be pushed only in specific areas within a health care agency. Confirm the institutional guidelines regarding requirements for special monitoring and verify that these requirements are available before giving medication.

2. Collect the information necessary to administer the medication safely, including action, purpose, side effects, normal dose, time of peak onset, the pace at which to give the medication, and nursing implications, such as the need to dilute the medication or to administer it through a filter.
3. If pushing the medication into an IV line, determine the compatibility of the medication both with the IV fluids and any additives in the IV solution.
4. Perform hand hygiene. Assess the IV or saline (heparin) lock insertion site for signs of infiltration or phlebitis (see Chapter 39).
5. Check the patient's medical history and allergies.
6. Check the date of expiration for the medication vial or ampule.
7. Assess the patient's understanding of the purpose of medication therapy.
8. Prepare the ordered medication from the vial or ampule using aseptic technique (see Skill 33-3). Check the label of the medication carefully with the MAR two times. Apply a removable label indicating the patient's name and the medication name and dosage to the removable needle cap.

- Intravenous medications are not always compatible with IV solutions and additives.
- Confirming the placement of the IV catheter and the integrity of the surrounding tissue ensures the medication is administered safely.
- The intravenous bolus delivers medication rapidly. Allergic reactions can be fatal.
- Drug potency sometimes increases or decreases when medications are expired.

Critical Decision Point: Some IV medications require dilution before administration. Verify the dilution requirements with the agency policy. If a small amount of medication is given (e.g., less than 1 mL), dilute the medication in 5 to 10 mL of normal saline or sterile water so that the medication does not collect in the "dead spaces" (e.g., the Y-site injection port or IV cap) of the IV delivery system.

Continued

► SKILL 33-7 Administering Medications by Intravenous Bolus—cont'd

9. Take the medication to the patient at the correct time.
 10. Identify the patient using at least two patient identifiers.
Compare the patient's name and one other identifier (e.g., the hospital identification number) on the MAR, computer printout, or computer screen against information on the patient's identification bracelet. Ask the patient to state his or her name if possible, for a third identifier.
 11. Compare the label of the medication with the MAR at the patient's bedside.
 12. Explain the procedure to the patient. Encourage the patient to report symptoms of discomfort at the IV site.
 13. Perform hand hygiene. Apply gloves.
 14. Administer the medication by IV push (through the existing IV line):
 - A. Select the injection port of the IV tubing closest to patient.
Whenever possible, the injection port should accept a needleless syringe. Use the IV filter if required by a medication reference manual or agency policy.
 - B. Wipe the injection port with an antiseptic swab. Allow to dry.
 - C. Connect the syringe to the IV line. Insert the needleless tip or a small-gauge needle of a syringe containing the prepared drug through the centre of the injection port (see Step 14C illustration).
 - D. Occlude the IV line by pinching the tubing just above the injection port.
- The *third check* of the medication label against the MAR at bedside reduces medication administration errors.
 - Asking the patient to report symptoms of discomfort helps in early identification of infiltration.
 - Hand hygiene reduces the transmission of infection. During IV bolus administration, the risk of blood exposure is low. However, you may need to manipulate the IV dressing or expose the site while you complete other activities. Gloves reduce your exposure.
 - The WHO (2005), Wilburn & Eijkemans (2004), Health Canada (1999), the CCOHS (2005), and the National Institute for Occupational Safety and Health (NIOSH) (1999), which is part of the Centers for Disease Control and Prevention (CDC), strongly recommend that all IV injection sites be needleless to prevent needle-stick injuries.
 - Wiping with an antiseptic swab prevents the introduction of microorganisms during needle insertion.
 - This procedure prevents damage to the port's diaphragm and subsequent leakage.
 - This step is the *final check* that the medication is being delivered into the bloodstream.

Step 14C Connecting the syringe to the IV line with a blunt needleless cannula tip.

Step 14D Intravenous line pinched above the injection port for medication infusion.

Critical Decision Point: In some cases, especially with a smaller gauge IV needle or a needleless device, the blood return may not be aspirated, even if the IV is patent (open and unblocked). If the IV site does not show signs of infiltration, and the IV fluid is infusing without difficulty, proceed with the IV push.

► SKILL 33-7 Administering Medications by Intravenous Bolus—cont'd

- E. Release the tubing and inject the medication within the amount of time recommended by institutional policy, the pharmacist, or a medication reference manual. Use your watch to time the administration (see Step 14E illustration). The IV line may be pinched while pushing medication and released when not pushing medication (see Step 14E illustration). Allow the IV fluids to infuse when the medication is not being pushed.

Step 14E A, Timing the IV push medication. B, The IV line is pinched off for medication infusion (optional).

- Following the proper procedure ensures safe medication infusion. Rapid injection of IV medication can prove fatal. Allowing the IV fluids to infuse while not pushing the IV drug enables medications to be delivered to the patient at a prescribed rate.

Critical Decision Point: If the IV medication is incompatible with IV fluids, stop the IV fluids, clamp the IV line, flush with 10 mL of normal saline or sterile water, give the IV bolus over the appropriate amount of time, flush with another 10 mL of normal saline or sterile water at the same rate as the medication was administered, and then restart the IV fluids at the prescribed rate. If the IV that is currently hanging is a medication, disconnect the IV, and administer the IV push as outlined in Step 14. This step avoids giving the patient a sudden bolus of the medication in the existing IV line and avoids creating potential risks associated with IV incompatibilities. Some IV medications and fluids cannot be stopped. Verify the institutional policy regarding the temporary stopping of IV fluids or continuous IV medications. If unable to stop the IV infusion, start a new IV site and administer the medication using the IV lock method.

- F. After injecting the medication, release the tubing, withdraw the syringe, and recheck the fluid infusion rate.
15. Administer medications by IV push (IV lock or a needleless system):
- A. Prepare the flush solutions according to agency policy. Ensure that a syringe with the correct barrel width is used. Consult with agency policy regarding syringes for delivering IV bolus medications.
- (1) Saline flush method (preferred method):
- (a) Prepare two syringes with 2–3 mL of normal saline (0.9%) in a syringe.
- (2) Heparin flush method (traditional method):
- (a) Prepare one syringe with the ordered amount of heparin flush solution.
- (b) Prepare two syringes with 2–3 mL of normal saline.
- Injection of the bolus may alter the rate of fluid infusion. Rapid fluid infusion can cause circulatory overload.
 - Small syringes with narrow bores (e.g., 1 mL or 3 mL) create greater pressure per square inch (PSI) when used to inject solutions into an IV line. A high PSI can damage the lumen of certain types of in-dwelling IV catheters (central lines and peripherally inserted central catheter [PICC] lines). Ensure that you consult with agency policy to ensure safe maintenance of these lines.
 - Normal saline has been found to be effective in keeping IV locks patent and is compatible with a wide range of medications.

Continued

► SKILL 33-7 Administering Medications by Intravenous Bolus—cont'd

B. Administer medication:

- (1) Wipe the lock's injection port with an antiseptic swab.
- (2) Insert a syringe containing normal saline into the injection port of the IV lock (see Step 15B2 illustration).

Step 15B (2) Syringe inserted into the injection port.

- (3) Pull back gently on the syringe plunger and look for blood return.

- Wiping the injection port prevents introduction of microorganisms during the needle insertion.

- This step determines whether the IV needle or catheter is positioned in the vein.

Critical Decision Point: Sometimes a saline (or heparin) lock will not yield a blood return even though the lock is patent. If the IV site does not show signs of infiltration, proceed with the IV push.

- (4) Flush the IV lock with normal saline by pushing slowly on the plunger.

- Flushing the IV lock clears it of blood.

Critical Decision Point: Observe closely the area of skin above the IV catheter. As the IV lock is flushed, note any puffiness or swelling, which could indicate infiltration into the vein, and thereby require removal of the catheter.

- (5) Remove the saline-filled syringe.
- (6) Clean the lock's injection port with an antiseptic swab.
- (7) Insert the syringe containing the prepared medication into the injection port of the IV lock.
- (8) Inject the medication within the amount of time recommended by institutional policy, the pharmacist, or a medication reference manual. Use a watch to time the administration.
- (9) After administering the bolus, withdraw the syringe.
- (10) Clean the lock's injection port with an antiseptic swab.
- (11) Attach the syringe with normal saline and inject the normal saline flush at the same rate that the medication was delivered.

- Cleaning the injection port prevents transmission of infection.
- Rapid injection of the IV medication can result in death. Following the guidelines for IV push rates promotes patient safety (Karch & Karch, 2003).

- (12) *Heparin flush option:* Insert the needle of the syringe containing the heparin through the diaphragm.

- Cleaning the injection port prevents transmission of microorganisms.
- Irrigation with saline prevents occlusion of the IV access device and ensures all medication is delivered. Flushing the IV site at the same rate as the medication ensures that any medication remaining within the IV needle is delivered at the correct rate.
- Inserting the needle through the diaphragm maintains the patency of the IV catheter and tubing by inhibiting clot formation. Use the SASH method: **S**aline, **A**dministration of medication, **S**aline, **H**eparin.
- Proper disposal reduces the risk of accidental needle sticks.
- Proper hygiene reduces the transmission of microorganisms.
- IV medications act rapidly.
- Swelling indicates infiltration into tissues surrounding the vein.
- IV bolus medications often cause rapid changes in the patient's physiological status. Some medications require careful monitoring and assessment and possible laboratory testing (e.g., vasopressors require the monitoring of blood pressure and heart rate; dilantin requires laboratory studies to determine whether it is at a therapeutic level).

16. Dispose of uncapped needles and syringes in puncture-proof and leak-proof container.
17. Remove and dispose of gloves. Perform hand hygiene.
18. Observe the patient closely for adverse reactions while the medication is administered and for several minutes thereafter.
19. Observe the IV site during injection for sudden swelling.
20. Observe the patient's status after administering the medication to evaluate the effectiveness of medication.

► SKILL 33-7 Administering Medications by Intravenous Bolus—cont'd

21. Consult with agency policy with regard to the frequency of saline flushes.
22. Ask the patient to explain the medication's purposes and side effects.

Unexpected Outcomes

Adverse reaction to medication

Symptoms of infiltration or phlebitis at intravenous site

Recording and Reporting

- Record the medication, dose, time, and route on the appropriate form (MAR) or in computer record.
- Report any adverse reactions immediately to the health care provider because the reactions could be life-threatening. The patient's response may indicate the need for additional medical therapy.
- Record the patient's response to medication in the nurses' notes.

- To maintain patency of intravenous catheters (peripheral or central), IV devices require routine flushing. Short-term peripheral angiocatheters are flushed every 12 hours with a normal saline solution. Consult with agency policy with regard to protocols for flushing central lines.

Related Interventions

- Stop delivering medication immediately and follow institutional policy or guidelines for the appropriate response and reporting of adverse drug reactions.
- Notify the patient's health care provider of adverse effects immediately.
- Add allergy information to the patient's medical record.
- Immediately discontinue administration of the injection and discontinue use of the site.
- Follow institutional guidelines on appropriate extravasation care.

setup, the main line does not infuse when the piggybacked medication is infusing. The port of the primary IV line contains a back-check valve that automatically stops flow of the primary infusion when the piggyback infusion flows. After the piggyback solution infuses and the solution within the tubing falls below the level of the primary infusion drip chamber, the back-check valve opens and the primary infusion again flows.

Tandem. A tandem setup is a small (25 to 100 mL) IV bag or bottle connected to a short tubing line that connects to the lower Y-port of a primary infusion line or to an intermittent venous access. The tandem set is placed at the same height as the primary infusion bag or bottle. In the tandem setup, the tandem and the main line infuse simultaneously. Monitor the tandem setup closely. If it is not immediately clamped when the medication is infused, the IV solution from the primary line will back up into the tandem line.

Mini-Infusion Pump. The mini-infusion pump is battery operated and allows medications to be given in very small amounts (5 to 60 mL) within controlled infusion times using standard syringes (Skill 33-8).

Intermittent Venous Access. An intermittent venous access (commonly called a heparin lock or saline lock) is an IV catheter with a small chamber covered by a rubber diaphragm or a specially designed cap (Figure 33-31). Special rubber-seal injection caps accept the needle safety devices and can be inserted into most IV catheters (see Chapter 39). Advantages to intermittent venous access include the following:

- Reduced risk of the patient developing fluid volume excess
 - Increased mobility, safety, and comfort for the patient
- Before administering an IV bolus or piggyback medication, assess the patency and placement of the IV site. After the medication has been administered through an intermittent venous access, the access must be flushed with a solution to keep it patent. In general, normal saline is an effective flush

Figure 33-31 Intermittent lock covered with a rubber diaphragm.

solution for peripheral catheters. Some institutions require the use of heparin. Verify and follow the institution's policies regarding the care and maintenance of the IV site.

Administration of IV Therapy in the Home. Sometimes patients may be discharged from an acute care setting and continue to receive IV therapy in the home setting. Medications such as antibiotics, chemotherapy, total parenteral nutrition, pain medications, and blood transfusions may be given in the home. Most patients who have home IV therapy will have a central venous catheter inserted before their discharge (see Chapter 39). In addition, patients who need to receive IV therapy in the home have home care nurses who assist in the management of the IV therapy.

However, patients and their families need to be carefully assessed for their ability to manage this therapy at home. Instruction on IV care management must be provided while the patient is still in the hospital. Patients and their families need to be taught how to recognize problems and what to do when these problems occur. It is important for the

Text continued on p. 747

► SKILL 33-8

Administering Intravenous Medications by Piggyback, Intermittent Intravenous Infusion Sets, and Mini-Infusion Pumps**Delegation Considerations**

The administration of medications by IV fluid by piggyback, intermittent IV infusion sets, and mini-infusion pumps cannot be delegated to unregulated care providers (UCPs). Instruct UCPs to report any unexpected drug reactions or discomfort at the infusion site as soon as possible.

Equipment

- Antiseptic swab
- IV pole
- Medication administration record (MAR) or computer printout
- Medication labels
- Piggyback, tandem, or mini-infusion pump:
- Medication prepared in 5- to 150-mL labelled infusion bag or syringe
- Short microdrip or macrodrip tubing set for piggyback (may have needleless system attachment)
- Needleless device or stopcocks if available
- Needles (21 or 23 gauge, only if stopcocks or other needleless methods are not available)
- Mini-infusion pump
- Adhesive tape (optional)
- Volume-control administration set
- Volutrol, Buretrol, or Pediatrol
- Infusion tubing (may have needleless system attachment)
- Syringe (1-20 mL)
- Vial or ampule of ordered medication

Procedure**STEPS**

1. Check the accuracy and completeness of each MAR or computer printout against the prescriber's original medication order. Check the patient's name and the medication name, route, dosage, and time of administration. Copy or rewrite any portion of the MAR that is difficult to read.
2. Determine the patient's medical history.
3. Collect the information necessary to administer the medication safely, including the action, purpose, side effects, normal dose, time of peak onset, and nursing implications.
4. Assess the compatibility of the drug with the existing IV solution.

RATIONALE

- The order sheet is the most reliable source and only legal record of medications patients are to receive. Checking the accuracy of the medication order ensures that the patient receives the correct medications. Illegible MARs are a source of medication errors.
- Information about the medication indicates the type of appropriate IV solution to use and helps to ensure safe and accurate medication administration.
- Drugs that are incompatible with IV solutions may result in clouding or crystallization of the solution in IV tubing, which may harm the patient.

Critical Decision Point: Never administer IV medications through tubing that is infusing blood, blood products, or parenteral nutrition solutions.

5. Assess the patency of the patient's existing IV infusion line by noting the infusion rate of the main IV line.

- The IV line must be patent and fluids must infuse easily for medication to reach the venous circulation effectively.

Critical Decision Point: If the patient's IV site is saline locked, clean the port with alcohol and assess the patency of the IV line by flushing it with 2–3 mL of sterile normal saline. Attach the appropriate IV tubing to the saline lock and administer the medication via piggyback, tandem, mini-infusion, or volume-control administration set. When the infusion is completed, disconnect the tubing, clean the port with alcohol, and flush the IV line with 2–3 mL sterile normal saline. Maintain sterility of the IV tubing between intermittent infusions.

6. Perform hand hygiene. Assess the IV insertion site for signs of infiltration or phlebitis: redness, pallor, swelling, tenderness on palpation.
7. Assess the patient's history of medication allergies.
8. Assess the patient's understanding of purpose of medication therapy.
9. Prepare the medication. Ensure that you compare the label of the medication with the MAR two times while preparing the medication.
10. Assemble the supplies at the bedside. Prepare the patient by explaining that the medication will be given through the IV equipment.

- Confirmation of placement of IV needle or catheter and integrity of surrounding tissues ensures medication is administered safely.
- The effects of medications can develop rapidly after IV infusion. You should be aware of patients who are at risk for an allergic reaction.
- Ensure that correct medication is given to patient. *First and second checks for accuracy ensure that the correct medication is administered.*

► SKILL 33-8

Administering Intravenous Medications by Piggyback, Intermittent Intravenous Infusion Sets, and Mini-Infusion Pumps—cont'd

11. Perform hand hygiene.
 12. Identify the patient using at least two patient identifiers. Compare the patient's name and one other identifier (e.g., the hospital identification number) on the MAR, computer printout, or computer screen against information on the patient's identification bracelet. Ask the patient to state his or her name, if possible, for a third identifier.
 13. Compare medication label with MAR at patient's bedside.
 14. Explain to the patient the purpose of the medication and its side effects. Encourage the patient to report symptoms of discomfort at the injection site.
 15. Administer the infusion:
 - A. Piggyback or tandem infusion
 - (1) Connect the infusion tubing to the medication bag (see Chapter 39). Allow the solution to fill the tubing by opening the regulator flow clamp. Once the tubing is full, close the clamp and cap the end of the tubing.
 - (2) Hang the piggyback medication bag above the level of the primary fluid bag. (A hook may be used to lower the main bag.) Hang the tandem infusion at same level as the primary fluid bag.
 - (3) Connect the tubing of the piggyback or tandem infusion to the appropriate connector on the primary infusion line:
 - (a) *Stopcock*: Wipe the stopcock port with an alcohol swab and connect the tubing. Turn the stopcock to the open position.
 - (b) *Needleless system*: Wipe the needleless port, and insert the tip of the piggyback or tandem infusion tubing (see Step 15A[3][b] illustrations).
- This process complies with the Joint Commission's (2007) requirements and improves medication safety. In acute care settings, the patient's name and identification number on an armband and the MAR are usually used to identify patients. Identification bracelets are made at the time of the patient's admission and are the most reliable source of information. The patient's room number is *not* an acceptable identifier.
 - *This is the third accuracy check.*
 - Communication with the patient keeps the patient informed of planned therapies. Patients who can verbalize pain at the IV site can help detect IV infiltrations early, reducing the possibility of damage to the surrounding tissues.
 - The infusion tubing should be filled with solution and free of air bubbles to prevent an air embolus.
 - The height of the fluid bag affects the rate of medication flow to the patient.
 - The WHO (2005), Wilburn & Eijkemans (2004), Health Canada (1999), the CCOHS (2005), and the CDC (NIOSH, 1999) strongly recommend that all IV injection sites be needleless to prevent needlestick injuries. The needleless system establishes the route for IV medication to enter the main IV line.

Step 15A(3)(b) A, Needleless lever lock cannula system. B, The blunt-ended cannula inserts into the port and locks.

- (c) *Tubing port*: Connect the sterile needle to the end of the piggyback or tandem infusion tubing, remove the cap, clean the injection port on the main IV line, and insert the needle or needleless access device through the centre of the port. Secure by taping the connection.
 - (4) Regulate the flow rate of the medication solution by adjusting the regulator clamp. (Infusion times vary. Refer to a medication reference manual or institutional policy for the safe flow rate.)
- Use this step *only* if the needleless system is not available. The tubing port prevents the introduction of microorganisms during needle insertion.
 - The proper flow rate provides a slow, intermittent infusion of medication and maintains therapeutic blood levels.

Continued

► SKILL 33-8

Administering Intravenous Medications by Piggyback, Intermittent Intravenous Infusion Sets, and Mini-Infusion Pumps—cont'd

(5) After medication has infused, check the flow regulator on the primary infusion. The primary infusion should automatically begin to flow after the piggyback or tandem solution is empty.

(6) Regulate the main infusion line to the desired rate, if necessary.

(7) Leave the IV piggyback bag and tubing in place for future medication administration or discard in appropriate containers.

B. Volume-control administration set (e.g., Volutrol)

(1) Assemble the supplies in the medication room.

(2) Prepare medication from a vial or ampule (see Skill 33-3).

(3) Fill the Volutrol with the desired amount of fluid (50–100 mL) by opening the clamp between the Volutrol and the main IV bag (see Step 15B[3] illustration).

- The back-check valve on the piggyback stops the flow of the primary infusion until the second medication infuses. The tandem and primary infusions flow together until the tandem set empties. Monitoring the flow rate ensures the proper administration of IV fluids.
- The infusion of the piggyback may interfere with the main line infusion rate.
- The establishment of a secondary line produces a route for microorganisms to enter the main line. Repeated changes in the tubing increase the risk of infection transmission (check agency policy).
- Use of the medication room controls the risk of contaminating the IV solution.
- Following proper procedure ensures the medication is sterile.
- Use of a small volume of fluid dilutes the IV medication and reduces the risk of too-rapid infusion.

Step 15B(3) Filling the volume control administration device.

(4) Close the clamp and ensure the clamp on the air vent of the Volutrol chamber is open.

(5) Clean the injection port on the top of the Volutrol with an antiseptic swab.

- Prevents additional leakage of fluid into the Volutrol. The air vent allows fluid in the Volutrol to exit at regulated rate.
- Cleaning the injection port prevents the introduction of microorganisms during needle insertion.

► SKILL 33-8

Administering Intravenous Medications by Piggyback, Intermittent Intravenous Infusion Sets, and Mini-Infusion Pumps—cont'd

- (6) Remove the needle cap or sheath and insert the syringe needle through the port, then inject the medication (see Step 15B[6] illustrations). Gently rotate the Volutrol between your hands.

- Rotating mixes the medication with the solution in the Volutrol to ensure equal distribution.

Step 15B(6) A, Medication injected into the device. B, The prepared device.

- (7) Regulate the IV infusion rate to allow the medication to infuse in the time recommended by institutional policy, a pharmacist, or a medication reference manual.
- (8) Label the Volutrol with the name of the medication, the dosage, the total volume (including the diluent), and the time of administration.
- (9) Dispose of the uncapped needle or the needle enclosed in safety shield and syringe in a proper container. Perform hand hygiene.

C. Mini-infusion administration

- (1) Connect the prefilled syringe to the mini-infusion tubing.
- (2) Carefully apply pressure to the syringe plunger, allowing the tubing to fill with medication.

- For optimal therapeutic effect, the medication should infuse in prescribed time interval.
- Proper labelling alerts nurses to medication being infused and prevents other medications from being added to the Volutrol.
- Proper disposal prevents accidental needle-stick injuries. Hand hygiene reduces the transmission of microorganisms.
- The special tubing is designed to fit the syringe to deliver the medication to the main IV line.
- Applying pressure ensures the tubing is free of air bubbles to prevent an air embolus.

Continued

► SKILL 33-8

Administering Intravenous Medications by Piggyback, Intermittent Intravenous Infusion Sets, and Mini-Infusion Pumps—cont'd

- (3) Place the syringe into a mini-infusor pump (follow product directions). Ensure the syringe is secure (see Step 15C[3] illustration).

Step 15C(3) Securing the syringe into a mini-infusor.

- (4) Connect the mini-infusion tubing to the main IV line.
- Stopcock:* Wipe the stopcock port with an alcohol swab and connect the tubing. Turn the stopcock to the open position.
 - Needleless system:* Wipe the needleless port and insert the tip of the mini-infusor tubing.
 - Tubing port:* Connect the sterile needle to the mini-infusion tubing, remove the cap, clean the injection port on the main IV line, and insert the needle through the centre of the port. Consider placing tape where the IV tubing enters the port to secure the connection.
- (5) Explain the purpose of the medication and the side effects to the patient and explain that the medication is to be given through the existing IV line. Ask the patient to report any symptoms of discomfort at the injection site.
- (6) Hang the infusion pump with the syringe on the IV pole alongside the main IV bag. Set the pump to deliver medication within the time recommended by institutional policy, the pharmacist, or a medication reference manual. Press the button on the pump to begin infusion. Optional: Set the alarm.
- (7) After medication has infused, check the flow regulator on the primary infusion. The infusion should automatically begin to flow once the pump stops. Regulate the main infusion line to the desired rate as needed. (Note: If the stopcock is used, turn off the mini-infusion line.)
- Observe the patient for signs of adverse reactions.
 - During infusion, periodically check the infusion rate and the condition of the IV site.
 - Ask the patient to explain the purpose and side effects of the medication.
- Use of the stopcock reduces the risk of needle-stick injuries.
 - Cleaning reduces the transmission of microorganisms.
 - Proper communication informs the patient of planned therapies.
 - The pump automatically delivers medication at a safe, constant rate, on the basis of the volume in the syringe. (An alarm is used if the medication is delivered into a heparin or saline lock.)
 - Proper flow maintains the patency of primary IV line.
 - IV medications act rapidly.
 - The IV must remain patent for proper medication administration. If infiltration develops, discontinue the infusion.
 - Asking the patient about the medication evaluates the patient's understanding of the instructions.

► SKILL 33-8

Administering Intravenous Medications by Piggyback, Intermittent Intravenous Infusion Sets, and Mini-Infusion Pumps—cont'd**Unexpected Outcomes***Adverse drug reaction**Medication does not infuse over desired period**Swelling, warmth, reddening, and tenderness at intravenous site, indicating phlebitis (see Chapter 39)**Coolness, pallor, and swelling at intravenous site (see Chapter 39)***Related Interventions**

- Stop medication infusion immediately.
- Follow institutional policy or guidelines for the appropriate response, assessments, and reporting of adverse drug reactions.
- Notify the patient's health care provider of adverse effects immediately.
- Document the allergy in the patient's medical record.
- Determine the reason for the lack of infusion (e.g., improper calculation of flow rate, wrong positioning of the IV needle at the insertion site, or infiltration).
- Take corrective action as indicated.
- Stop IV infusion.
- Discontinue IV.
- Treat the IV site as indicated by the institutional policy.
- Insert a new IV site if continuation of therapy is indicated.
- Signs of infiltration are indicated.
- Some IV medications are extremely harmful to subcutaneous tissue.
- Provide IV extravasation care as indicated by institutional policy; or use a medication reference manual or consult a pharmacist to determine the appropriate follow-up care.

Recording and Reporting

- Record the medication, dose, route, and time administered on the MAR or computer printout.
- Record on the intake and output from the volume of fluid in the medication bag or Volutrol.
- Report any adverse reactions to the nurse in charge or the physician.

Home Care Considerations

- Teach the patient and caregiver to dispose of needles and contaminated equipment in puncture-proof containers (e.g., a coffee can).
- Instruct the patient's family about community resources for obtaining supplies.
- Collaborate with the interdisciplinary team to facilitate access to supplies for patients who have both physical and geographical barriers.

patient's family to recognize signs of infection and complications and to know that when these signs occur, the home care nurse or physician must be notified. In addition, patients and their families need information regarding the maintenance of IV administration equipment, including the infusion pump.

Subcutaneous Butterfly Catheters. Subcutaneous butterfly catheters provide a route for both subcutaneous medication administration and hypodermoclysis (Box 33-26). As a route for medication administration, subcutaneous butterfly catheters reduce the frequency of breaking the skin barrier to inject a medication. This route is used for patients requiring longer-term therapy with medication that is administered via subcutaneous injection. **Hypodermoclysis** is the administration of fluids through a butterfly catheter and is commonly used for patients with limited intravenous access, palliative care patients, and patients at risk for or with mild dehydration.

A fine-gauge needle (e.g., 24-gauge) is inserted into the patient's subcutaneous tissue. The preferred site for subcutaneous butterfly catheters is the subcutaneous tissue of the abdomen. Other appropriate sites include the subcutaneous tissue of the upper arms, upper back (scapular area), anterior thighs, and the anterior upper chest (avoiding the breast and axilla). Do not insert a subcutaneous butterfly catheter into

tissues that have recently been irradiated or where a rash, bruising, or scar tissue is present. After inserting a subcutaneous butterfly catheter, only one type of medication can be injected (e.g., morphine).

Contraindications to using the hypodermoclysis route for IV fluid administration include cardiac failure, prerenal or renal failure, low platelet or coagulation disorders, and existing fluid overload or marked edema (see Chapter 39). If a patient is severely dehydrated, the intravenous route is preferred for fluid administration.

❖ KEY CONCEPTS

- Learning the medication classifications improves your understanding of nursing implications for administering medications with similar characteristics.
- Federal medication legislation regulates the production, distribution, prescription, and administration of medications.
- All controlled substances are handled according to strict procedures that account for each medication.
- Apply your understanding of the physiology of medication action when physically assessing a patient before medication, timing the administration, selecting routes, initiating actions to promote medication efficacy, and observing responses to medications.

► BOX 33-26 Procedural Guideline

Subcutaneous Butterfly Catheters and Hypodermoclysis

Delegation Considerations:

The insertion of subcutaneous butterfly catheters cannot be delegated. Instruct unregulated care providers to report the occurrence of side effects of medications immediately.

Equipment:

- Butterfly catheter with 24-gauge, 19-mm needle (the smallest and shortest gauge should be used)
- Interline injection site
- Antiseptic swab
- Occlusive dressing (Tegaderm or Opsite)
- Tape
- Clean gloves

Subcutaneous Medication Administration

- Ordered medication
- Syringe and needleless access device

Hypodermoclysis

- Ordered IV fluid
- IV administration set

Procedure:

1. Check the accuracy and completeness of each medication administration record (MAR) or computer printout against the prescriber's original medication order. Check the patient's name and the medication name, route, dosage, and time of administration. Copy or rewrite any portion of the MAR that is difficult to read.
2. Assess the patient's medical history, medication history, and history of allergies; know the substances the patient is allergic to and the allergic reaction.
3. Check the date of expiration for the medication.
4. Assess the adequacy of adipose tissue and any contraindications, such as rash, bruising, or scar tissue.
5. Remove the butterfly catheter from the package (see Step 5 illustration). Replace the existing cap with an interlink injection site.

Step 5 Subcutaneous butterfly catheters. **Source:** Courtesy Lynne Thibeault, Confederation College, Thunder Bay, ON.

6. *Subcutaneous medication administration:* Aseptically prepare the correct medication dose from an ampule or vial (see Skill 33-3). Ensure all air is expelled. Check the label of the medication with the MAR two times while preparing the medication. Replace the needle with a needleless injection device, clean the interlink injection port with an aseptic swab, and prime the subcutaneous catheter tubing. *Hypodermoclysis:* Attach the IV line to the interlink injection site on the subcutaneous butterfly catheter device and prime the unit.
7. Take the medication to the patient at the right time and perform hand hygiene.
8. Close the room curtain or door to provide privacy.
9. Identify the patient using at least two identifiers. Compare the patient's name and one other identifier (e.g., the hospital identification number) on the MAR, computer printout, or computer screen against information on the patient's identification bracelet. Ask the patient to state his or her name, if possible, as a third identifier.
10. Compare the label of the medication with the MAR one more time at the patient's bedside.
11. Explain to the patient the steps of the procedure and the sensations to expect, including a slight burning or stinging when the catheter is inserted. Inform the patient that the catheter will remain and will be used for medication administration of a particular medication.
12. Keep a sheet or gown draped over the body parts not requiring exposure.
13. Apply clean gloves.
14. Select an appropriate injection site. Inspect the skin surface over the sites for bruises, inflammation, or edema.
15. Palpate the sites for masses or tenderness. Avoid these areas.
16. Assist the patient into a comfortable position; have the patient relax the abdomen, thigh, or upper arm, depending on selected site.
17. Locate the site using appropriate anatomical landmarks.
18. Clean the site with an antiseptic swab. Apply the swab at the centre of the site and rotate outward in a circular direction for about 5 cm.
19. Remove the sheath from the catheter needle by pulling it straight off.
20. Hold the subcutaneous butterfly wings between the thumb and forefinger of your dominant hand with the palm down.
21. Ensure the bevel of the needle is pointed upward.
22. Using the thumb and index finger of your nondominant hand, gently pinch the patient's skin around the selected injection site to create a roll of skin 1.25 to 2.5 cm in diameter.
23. Insert the full length of the needle through the skin at a 30-degree angle.
24. Assess for blood return into the catheter tubing. If blood return occurs, withdraw the needle and repeat the procedure at a new site.
25. Release the catheter wings and stabilize them on the skin surface with your thumb and index finger.
26. Apply an occlusive dressing (e.g., Tegaderm, Opsite) over the insertion site and some of the tubing. Reinforce the dressing with tape.

► BOX 33-26 Procedural Guideline—cont'd

27. Apply a label to the occlusive dressing that shows the date and time of administration and your initials.
28. *Subcutaneous medication administration:* Wipe the interlink injection port with an antiseptic swab and administer the medication. *Hypodermoclysis:* Adjust the flow rate of IV fluids according to the physician's order.

29. Dispose of the syringe with the needleless injection device into a sharps container.
30. Remove gloves and discard. Perform hand hygiene.
31. Document the procedure, including the site, type, and gauge of subcutaneous butterfly catheter; the date and time of insertion; the patient's response to the insertion; and your initials.

- The older adult's body undergoes structural and functional changes that alter medication actions and influence the way in which medication therapy is provided.
- Children's medication doses are computed on the basis of body surface area and weight.
- Medications given parenterally are absorbed more quickly than medications administered by other routes.
- Each medication order should include the patient's name; the order date; the medication name, dosage, route, time of administration, and indication; and the prescriber's signature.
- A medication history reveals allergies, medications that the patient is taking, and the patient's compliance with therapy.
- The nursing process should be used when administering medication.
- The 10 rights of medication administration ensure accurate preparation and administration of medication doses.
- The 10 rights of medication administration are the right medication, right dose, right patient, right route, right time and frequency, right documentation, and right reason, right evaluation (or assessment), right patient education, and right to refuse.
- Administer only the medications that you prepare; never leave prepared medications unattended.
- Avoid distractions and follow the same routines when preparing medications to reduce the chance of medication errors.
- Never recap needles.
- To prevent medication errors, document immediately all medications you administer.
- Use your clinical judgement to determine the best time to administer "prn" (when needed) medications.
- Report medication errors immediately.
- When preparing medications, check the medication container label against the medication administration record three times.
- The Z-track method for intramuscular injections protects the subcutaneous tissues from irritating parenteral fluids.
- Failure to select injection sites by anatomical landmarks may lead to tissue, bone, or nerve damage.

✦ CRITICAL THINKING EXERCISES

1. Mrs. Nguyen, a 69-year-old woman, has recently experienced a stroke and has right-sided weakness. The neurological clinical nurse specialist wrote orders to start oral medications today. What steps do you take to ensure that this patient can safely receive her oral medications? What do you do if the patient is unable to swallow?
2. Marissa is a 25-year-old woman who recently delivered a healthy infant. She is to receive RhoGAM 300 mcg IM today. What size needle and which injection site and technique do you use to administer this medication?
3. Jack, a 70-year-old retired farmer, has been experiencing new respiratory difficulties. His physician has ordered him to start

using an albuterol inhaler with a spacer. What steps do you take to ensure that he can self-administer his metered-dose inhaler?

4. You receive an order to give furosemide (Lasix) 40 mg IV push. You have never given this medication on this unit. What steps do you take before administering the Lasix?

✦ REVIEW QUESTIONS

1. Which of the following rights has been added to the ten rights of medication administration?
 1. Right to refuse
 2. Right route
 3. Right medication
 4. Right patient
2. You are having difficulty reading a physician's order for a medication. You know the physician is very busy and does not like to be called. What do you do?
 1. Call a pharmacist to interpret the order.
 2. Call the physician to have the order clarified.
 3. Consult the unit manager to help interpret the order.
 4. Ask the unit secretary to interpret the physician's handwriting.
3. A patient has a gastrointestinal alteration. Which method of medication administration should *not* be used?
 1. Oral
 2. Topical
 3. Inhalation
 4. Injection
4. Most medication errors occur when the nurse
 1. Fails to follow routine procedures
 2. Is responsible for administering numerous medications
 3. Is caring for too many patients
 4. Is administering unfamiliar medications
5. A patient is to receive cephalexin (Keflex) 500 mg PO. The pharmacy has sent 250 mg tablets. How many tablets should you give?
 1. 0.5 tablet
 2. 1 tablet
 3. 1.5 tablets
 4. 2 tablets
6. A medication injection into the loose connective tissue under the dermis is known as what kind of injection?
 1. An intramuscular injection
 2. An intravenous injection
 3. A subcutaneous injection
 4. An intradermal injection

7. You are responsible for following legal provisions when administering controlled substances or narcotics. What may be the result of your failure to comply?
 1. Fines, imprisonment, and loss of nurse licensure
 2. Loss of employment
 3. Medication errors
 4. Poor health outcomes resulting from narcotic use
8. Pharmacokinetics is the study of how medications
 1. Are derived from plants
 2. Enter the body, reach their site of action, are metabolized, and exit the body
 3. Are used for certain disease processes
 4. Are manufactured and distributed to pharmaceutical companies
9. Which of the following is an official publication that sets standards for medication strength, quality, purity, packaging, safety, labelling, and dose form?
 1. *Physicians Reference Guide*
 2. *Nurse's Drug Guide*
 3. *Narcotic Control Act*
 4. *The Canadian Formulary (CF)*
10. Who is responsible for the administration of the *Food and Drugs Act* and the *Controlled Drugs and Substances Act*?
 1. Health Protection Branch (HPB)
 2. Nurse or physician dispensing and prescribing medications
 3. *Canadian Formulary*
 4. Health care institutions

✚ RECOMMENDED WEB SITES

Canadian Pharmacists Association: <http://www.pharmacists.ca>
The Canadian Pharmacists Association (CPhA) is a national organization of pharmacists. CPhA's Web site provides links to drug information, patient information, and resources.

Health Canada: Drug Products: <http://www.hc-sc.gc.ca/dhp-mpps/prodpharma/databasdon/index-eng.php/>

This Web site provides access to government reports, resources, and programs about the safety and effectiveness of pharmaceutical drugs and other therapeutic products.

Health Canada Therapeutic Products Directorate: <http://www.hc-sc.gc.ca/ahc-asc/branch-dirgen/hpfb-dgpsa/tpd-dpt/index-eng.php>

Health Canada's Therapeutic Products Directorate is the Canadian federal authority that regulates pharmaceutical drugs and medical devices for human use. This Web site provides access to information on reporting adverse reaction information.

Saskatchewan Drug Information Service: <http://druginfo.usask.ca/>

The Saskatchewan Drug Information Service (SDIS), operating from the University of Saskatchewan, aims to give health care providers and laypersons access to objective and concise information on drugs and drug therapy.

Complementary and Alternative Therapies

Written by Jean McClennon-Leong, RN, MN, FNP-BC, APNP

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Differentiate between complementary and alternative therapies.
- Discuss the relaxation response and its effect on somatic ailments.
- Identify the principles and effectiveness of imagery, meditation, and breathwork.
- Describe the purpose and principles of biofeedback.
- Describe the methods of and psychophysiological responses to therapeutic touch.
- Explain the scope of chiropractic therapy.
- Discuss the principles and applications of acupuncture.
- Describe the effect of nutrition on disease prevention and health promotion.
- Describe safe and unsafe herbal therapies.

The philosophy of **holistic health** is not new. Holistic health takes into account and sees as a whole, all aspects of people's needs, psychological, physical and social. Aristotle first proposed that the body and mind could not be separated and that a healer must observe and reflect upon the total person. Ancient civilizations dating from 5000 B.C., including the Egyptians and Chinese, were employing and recording the effects of various herbal and energy therapies on the body. Despite the Dark Ages (1493–1541), a period in human history characterized by a loss of interest in science and an increase in magic to explain the world environment, interest in the human condition continued to grow. The roots of twentieth-century conventional medicine (**allopathic medicine**) can be traced to René Descartes (1595–1650), a deeply religious mathematician and philosopher who believed that the mind and body must be separated to protect the "spirit" from scientific inquiry. Consequently,

the development of medicine focused exclusively on physical function and reduction of the larger whole into examination of the smaller parts (Rakel & Weil, 2007). This is still evident as seen by the various fields of specialization that occur within modern medical practices. Florence Nightingale (1820–1910), the founder of modern nursing, practised a holistic approach to health. She incorporated various healing modalities along with cleanliness, sanitation, and psychological support to soldiers during the Crimean War.

At the middle of the twentieth century, cultural shifts and paradigm changes occurred. Social activism was growing, and the birth of feminism, ecology, and the consumer and civil rights movements were altering market forces and attitudes toward traditional health care delivery systems. These social movements coincided with demographic changes, increased cultural diversity, and global mobility. Ultimately, this led consumer interest toward a person-centred, empowered approach to health. People desired a different kind of health care: one that embraced healing, acknowledgement of the spiritual dimensions of health and illness, and openness toward alternative medical systems. Today, the public has enormous access to information about personal health through the Internet and organizations such as the Canadian Holistic Nurses Association.

Complementary and Alternative Medicine Therapies in Health Care

Complementary and alternative medicine (CAM) therapies are not considered a part of conventional medicine. The terms are often used interchangeably but have different meanings. **Complementary therapies** are used together with conventional medical treatments, while **alternative therapies** are used instead of conventional therapy. As its name implies, complementary therapies complement, or contribute to and enhance, conventional health care treatment. Many complementary therapies, such as acupuncture, require diagnostic and therapeutic methods specific to their field, whereas other complementary therapies, such as imagery and breathwork, are, in general, easily learned and applied. Other complementary therapies are relaxation, massage (Figure 34-1), reflexology, prayer, biofeedback, and creative therapies such as art, music,

and dance (Figure 34-2) (Fontaine, 2005). You need to become knowledgeable about the safety and efficacy of these various therapies in order to advise patients effectively and wisely.

Alternative therapies are those modalities and treatments used instead of allopathic medical care and have often been negatively viewed as interfering with compliance in the use of conventional therapies. It is often difficult to clearly define what CAM is, as it varies between cultures, availability of services, and institutions. However, recent trends suggest that developing a healthy lifestyle by promoting wellness and preventing illness and disease may be achieved by a variety of means, including the use of CAM (Rakel & Weil, 2007). CAM therapies have become a growing consumer movement, and the preferred term when describing this phenomenon is **integrative medicine**. Integrative medicine focuses on evidence-informed research to integrate CAM into current health care models so that health and healing can be facilitated with safety and effectiveness (Koopsen & Young, 2009). One major premise of this concept includes the belief that all health care providers provide the best treatment for their patients, while respecting their health care choices. In this way, integrative medicine focuses on healing, rather than disease, and allows for multiple disciplines in providing care.

Complementary and alternative therapies are often organized into five categories that researchers find useful (Box 34-1). Some types of complementary and alternative therapies are presented in Table 34-1. This list is not exhaustive and does not address issues of safety and efficacy.

Public Interest in Complementary and Alternative Medicine Therapies

Increasingly, the boundaries between CAM and allopathic medicine are being eroded. The interest in CAM is evident in the increased number of articles about it in respected medical journals and the development of several journals specific to CAM. Some universities are adding courses about CAM therapies to their medical and nursing curricula, and colleges offer certificate courses in a variety of alternative therapies (University of York Department of Health Sciences, 2008). **Integrative medical programs** are being developed to provide health care consumers with access to both allopathic and complementary practitioners. In some institutions, for example, nurses practise massage, reiki, and therapeutic touch.

Figure 34-1 Massage therapy can effectively relieve tension.

Figure 34-2 Young adults participating in dance therapy.

► BOX 34-1 Categories of Complementary and Alternative Medicine (CAM) Therapies

Whole Medical Systems

Alternative medical systems encompass both theories and practices. Often, they evolved earlier than the conventional Western medical approach. Examples of alternative medical systems that have developed in Western cultures are homeopathic medicine and naturopathic medicine. Systems that have developed in non-Western cultures include traditional Chinese medicine and Ayurveda (which originated in India).

Mind-Body Interventions

Mind-body interventions use a variety of techniques designed to enhance the mind's capacity to affect bodily function and symptoms. Some techniques that were considered CAM in the past have become mainstream (e.g., patient support groups and cognitive-behavioural therapy). Other mind-body techniques that are still considered CAM are meditation, prayer, mental healing, art therapy, music therapy, and dance therapy.

Biologically Based Therapies

Biologically based therapies use substances found in nature, such as herbs, foods, and vitamins. Examples are dietary supplements, probiotics, herbal products, and other so-called natural but as yet scientifically unproven therapies (e.g., shark cartilage to treat cancer). Some uses of dietary supplements have been incorporated into conventional

medicine. For example, folic acid is used to prevent certain birth defects, and a regimen of vitamins and zinc can slow the progression of age-related macular degeneration, an eye disease that can lead to vision loss.

Manipulative and Body-Based Therapies

Manipulative and body-based therapies include a broad range of Eastern and Western movement therapies designed to improve overall well-being. Examples are massage therapy, chiropractic or osteopathic manipulation, and Feldenkrais.

Energy Therapies

Energy therapies involve the manipulation of energy fields to affect health. Energy therapies can be divided into two types:

- Biofield therapies are intended to affect the energy fields that purportedly surround and penetrate the human body. The existence of such fields has not been scientifically proven. Biofield therapies involve applying pressure or manipulating the body by placing the hands in or through these fields. Examples of biofield therapies are qigong, reiki, and therapeutic touch.
- Bioelectromagnetism-based therapies involve the unconventional use of measurable electromagnetic fields, such as pulsed, magnetic, or alternating or direct current fields.

► TABLE 34-1 Complementary and Alternative Therapies

Types	Mechanism or Philosophy of Action
Whole Medical Systems	
Ayurveda	This traditional Hindu system of medicine dates to ancient India. Ayurveda practitioners use a combination of remedies, such as herbs, purgatives, and oils, to treat disease.
Latin American practices	The curanderismo medical system includes a humoral model (the model used by Hippocrates to explain disease) for classifying food, activity, drugs, illnesses, and a series of folk illnesses.
Traditional Aboriginal medicine	This healing practice promotes harmony within a community and in the physical and spiritual worlds through sweating and purging, herbal remedies, and shamanic healing.
Naturopathic medicine	This system of therapeutics is based on natural foods, light, warmth, massage, fresh air, regular exercise, and avoidance of medications. Naturopathic medicine recognizes the body's inherent healing abilities. The treatments integrate traditional natural therapies with modern diagnostic sciences and may include botanical (plant) medicine.
Traditional Chinese medicine	These traditional and systematic techniques and methods promote health and treat disease through acupuncture, herbal remedies, massage, acupressure, qigong (balancing energy flow through movement), and moxibustion (the use of heat from burning herbs). The fundamental concepts of traditional Chinese medicine are embedded in Taoism, Confucianism, and Buddhism.
Biologically Based Therapies (Natural Health Products)	
Herbal remedies	These supplements contain a plant, plant part, or herb that is used singly or in mixtures to convey a health or therapeutic benefit.
Homeopathic medicines	This system of medicinal treatments is based on the theory that certain diseases can be cured with small doses of substances that, in a healthy person, would produce symptoms similar to the symptoms of disease. The prescribed remedies are made from naturally occurring plant, animal, or mineral substances.
Vitamins and minerals (megavitamin therapy)	This therapy promotes the increased intake of nutrients, such as vitamin C and beta carotene. The treatment focus is on cancer, schizophrenia, and certain chronic diseases, such as hypercholesterolemia and coronary artery disease.
Traditional medicines (Ayurvedic remedies) (traditional Chinese herbal remedies)	Ayurvedic remedies: Combinations of herbs, purgatives, and rubbing oils are used to treat disease. Herbs are considered the backbone of medicine. More than 50,000 medicinal plant species exist, many of which have been studied extensively.

Continued

► **TABLE 34-1** Complementary and Alternative Therapies—cont'd

Types	Mechanism or Philosophy of Action
Probiotics	These live microorganisms are orally administered to confer a protective benefit upon the immune system of the small intestine.
Amino acids, essential fatty acids (EFAs), and antioxidant supplements	These products are packaged as tablets or capsules that may have a beneficial effect on reducing the body's inflammatory response and limiting oxidative stress within the body.
Nutrition as Medicine	
Gerson therapy	This therapy advocates a low-salt, high-potassium organic diet of fruit juices, raw vegetables, and nutritional supplements, plus coffee enemas for detoxification. According to this therapy, disease is believed to be caused by the accumulation of toxic substances that disrupt the body's immune system. Gerson therapy is used primarily in the treatment of cancer.
Macrobiotic diet	This predominantly vegan diet (white meat fish, occasional fruits, seeds, and nuts) is believed to have anticancer properties. The diet consists of 40%–60% whole cereal grain, 20%–30% vegetables, 5%–10% beans.
Mediterranean diet	This diet, characteristic of people living in the Mediterranean region, is high in whole grains, nuts, fruits, vegetables, and omega-3 essential fatty acids. Following this diet is believed to produce a protective benefit for cardiac health and various inflammatory diseases.
Manipulative and Body-Based Therapies	
Acupressure	In this therapeutic technique, digital pressure is applied in a specified way on designated body points to relieve pain, produce analgesia, or regulate bodily function.
Chiropractic medicine	This therapy involves the manipulation of the spinal column and may include physiotherapy and diet therapy.
Feldenkrais method	This therapy is based on establishing good self-image through awareness and correction of body movements. The technique integrates the impact of physics on body movement patterns with how people move, behave, and interact.
Tai chi	This technique incorporates breath, movement, and meditation to cleanse, strengthen, and circulate vital energy and blood. Tai chi helps to stimulate the immune system and maintain balance.
Massage therapy	The manipulation of soft tissue through stroking, rubbing, or kneading increases the body's circulation and improves muscle tone and relaxation.
Simple touch	Touching the patient in appropriate, gentle ways stimulates connection, displays acceptance, and gives appreciation.
Mind-Body Interventions	
Aromatherapy	Essential plant oils are used to promote relaxation or stimulation, thereby enhancing overall well-being.
Art therapy	Art is used to reconcile emotional conflicts, foster self-awareness, and express frequently subconscious concerns.
Biofeedback	Instruments are used to provide a person with visual or auditory information about autonomic physiological body functions, such as muscle tension, skin temperature, and brain wave activity.
Breathwork	A variety of breathing patterns are used to relax, invigorate, or open the emotional channels.
Dance therapy	Dance is used to treat social, emotional, cognitive, or physical problems.
Hypnotherapy	The induction of trance states and the use of therapeutic suggestion are used to treat paralysis, headaches, addictions, pain, and phobias.
Imagery	This therapeutic technique is used to treat pathological conditions by concentrating on an image or series of images.
Labyrinth meditation	Labyrinths are ancient spiritual symbols found in almost every religious tradition. Walking the labyrinth is regarded as an ancient spiritual act of meditation, a time for reflection and prayer, and a pilgrimage.
Meditation	This self-directed practice relaxes the body and calms the mind by focusing on rhythmic breathing.
Music therapy	Music meets the physical, psychological, cognitive, and social needs of individuals with disabilities and illness. Music therapy is used to manage pain and to improve physical movement, communication, emotional expression, and memory.
Prayer therapies	A variety of techniques are used in many cultures to incorporate caring, compassion, love, and empathy. Prayer can be verbal or silent, a solitary or group activity, and can include chanting, visualizations, and rituals.
Psychotherapy	Mental and emotional disorders are treated by the use of psychological techniques.

► TABLE 34-1 Complementary and Alternative Therapies—cont'd

Types	Mechanism or Philosophy of Action
Yoga	Exercise, postures, regulated breathing, and meditation are used to attain physical and mental well-being. The practice focuses on the body's musculature, posture, breathing, and consciousness.
Energy Medicine	
Qigong	Qigong is derived from the ancient Chinese practice of breathing, movement, and meditation and involves the assuming of basic postures. This practice is believed to promote strength, balance, and optimal body functioning. Qigong is used to treat stress-related conditions, fatigue, and musculoskeletal stiffness.
Reiki therapy	Derived from ancient Buddhist practices in which a practitioner places a hand on or above the body and transfers “universal life energy” to the patient, the energy from this therapy provides strength, harmony, and balance to treat health issues.
Therapeutic touch	In this therapy, a practitioner directs his or her balanced energies toward the energies of a patient by laying the hands on or close to a patient's body.

In Canada and worldwide, demand is growing for alternative medicines and the services of alternative health care providers (Andrews & Boon, 2005; University of York Department of Health Sciences, 2008). A study released by the Fraser Institute (2007) indicated that 54% of respondents had used at least one form of complementary or alternative therapy and that 74% of Canadians had used CAM at some point during their lifetimes. Commonly used therapies included massage, prayer, chiropractic care, relaxation techniques, and herbal therapies. In another Canadian study, people with asthma, diabetes, and migraine visited a CAM provider at a significantly higher rate than those within the general population (Metcalf et al., 2010). The Canadian Interdisciplinary Network for CAM Research (IN-CAM) was created in 2004 to foster CAM research and disseminate information. Objectives include providing information reflecting the Canadian perspective on the safety and efficacy of various CAM products and therapies.

Although CAM therapies are less expensive and less invasive than allopathic medicine, and their use could save the health care system money, patients (or their private insurance plans) must pay for these therapies. Therefore, many patients cannot afford CAM therapies. The individuals who use CAM therapies typically are women with a post-high school or college-equivalent education (Bardia et al., 2007).

Complementary and Alternative Medicine Therapies and Holistic Nursing

The practice of holistic nursing regards and treats the patient's mind, body, and spirit. Nurses can use holistic interventions such as relaxation therapy, imagery, music therapy, simple touch (especially helpful with older patients; Box 34-2), massage, and prayer (Box 34-3). Such interventions affect the whole person and are economical, noninvasive, nonpharmacological complements to traditional medical care. Holistic interventions can augment standard treatments, replace ineffective or debilitating interventions, and promote and maintain health (Dossey & Keegan, 2013). The Canadian Holistic Nurses Association develops standards of practice for holistic nursing and promotes holistic nursing practice, education, research, and administration (Canadian Holistic Nurses Association, 2008).

Growing appreciation for the importance of healing both the spirit and body has influenced the development of such

BOX 34-2 FOCUS ON OLDER ADULTS

- Touch is a primary need and is as necessary to humans as food, growth, and shelter. Touch refers to a broad range of techniques for the purpose of assisting the recipient toward optimal health (Keegan & Shames, 2005).
- Older adults need touch as much as, or more than, any other age group. However, skin hunger or poverty of touch can be acute among older adults, who often have fewer family members or friends to touch them.
- Simple touch can be an enhanced form of communication when the other senses are reduced (Dossey & Keegan, 2013).
- Simple touch helps older adult patients feel more connected to their environment and accepted by those around them. The act of touching can enhance the older patient's self-esteem and sense of worth.

hospital programs as music therapy, art therapy, and recreation therapy. At the University of Alberta Hospital in Edmonton, the Artists on the Wards program connects local artists with individual patients at the bedside. This program helps patients develop their creativity, which may aid physical, spiritual, emotional, and mental healing. The hospital also houses the McMullen Art Gallery (Figure 34-3). Many hospitals now provide space for spiritual practice, and chaplains are widely regarded as part of the health care team. For instance, the University of Alberta Hospital offers patients and families both a chapel and a teepee. The teepee, built specifically for Aboriginal patients and their families, is used for prayer, reflection, and healing ceremonies (Figure 34-4). A few hospitals have or are considering the construction of labyrinths on their grounds. Patients and visitors can use these labyrinths for walking, meditation, and prayer (see Table 34-1).

The following sections discuss several types of complementary and alternative medicine therapies. The therapies are organized into two types. The first are nursing-accessible therapies. These are therapies that you can begin to learn and apply in patient care. The second type includes training-specific therapies, such as chiropractic therapy or acupressure, which a nurse cannot perform without additional training. Some of these therapies also require certification.

BOX 34-3 RESEARCH HIGHLIGHT

Tai Chi as an Intervention to Improve Balance and Reduce Falls in Older Adults

Research Focus

Tai chi is a traditional Chinese martial art that involves slow, rhythmic, and gentle movements designed to promote the unrestricted and peaceful flow of energy throughout the body. Studies suggest that tai chi may improve balance and reduce falls in older adults. Loss of muscle mass and strength can decrease balance and increase the risk of falls, and falls are the leading cause of injury in older individuals. Physical exercise programs for the elderly that are safe and effective should be part of health promotion because of the beneficial effects of exercise on posture, balance, and strength.

Research Abstract

Leung et al. (2011) conducted a meta-analysis of 13 randomized controlled trials to determine if tai chi improved balance and reduced falls in the elderly. All studies compared those practising tai chi to control groups receiving no treatment. A total of 2151 individuals participated in these trials, and while most of them were healthy, some had osteoporosis and osteoarthritis. Different styles of tai chi and length and duration of the programs varied. Fall counts were measured and various balance outcome measures were utilized. Based on this large review, it was concluded that tai chi reduced falls and improved balance in older, non-frail adults.

Evidence-Informed Practice

- Nurses caring for aging adults are in an ideal position to assess and recommend specific exercise and movement activities that would be most beneficial for their patients.
- Tai chi is regarded as an easy-to-follow and enjoyable exercise that can be recommended as a safe exercise modality.
- Proper screening for frailty in the older adult should be done prior to participating in a tai chi program, and nurses can determine the appropriateness of this modality for their patients.
- Nurses are a reliable source for determining if patient outcomes for tai chi exercise and movement are successfully achieved.

Reference: Leung, D., Chan, C., Tsang, H., Tsang, W., & Jones, A. (2011). Tai Chi as an intervention to improve balance and reduce falls in older adults: A systematic and meta-analytical review. *Alternative Therapies in Health and Medicine*, 17(1), 40–49.

Nursing-Accessible Therapies

Some CAM therapies and techniques use natural processes, such as breathing, concentration, and simple touch, to help patients feel better and cope with their chronic conditions. You can learn these techniques with minimum preparation, and many of these procedures can be used with patients as an independent nursing practice (Dossey & Keegan, 2013). Adequate assessment and the patient's permission are prerequisites for implementing these therapies. Some CAM therapies may alter physiological responses such that physician-prescribed therapies (e.g., drug doses) may need to be changed. CAM therapies should be chosen according to the patient's functional status, beliefs or religious perspectives, access to health care, and insurance coverage (Box 34-4).

These therapies are designed to teach patients how they can change their behaviour to alter their physical responses to stress and relieve such symptoms as muscle tension, gastrointestinal discomfort, pain, and sleep disturbances. One of the

Figure 34-3 McMullen Art Gallery, University of Alberta Hospital, is open to visitors, staff, and patients. **Source:** Courtesy of the University of Alberta Hospital, Edmonton, Alberta.

Figure 34-4 This teepee outside the University of Alberta Hospital in Edmonton is available for prayer, meditation, and sacred ceremony. **Source:** Courtesy of the University of Alberta Hospital, Edmonton, Alberta.

principles of these therapies is that the individual must be actively involved in the treatment. Patients achieve better responses if they practise the techniques or exercises daily. The patient must commit to implementing and maintaining the therapy until a desired outcome is achieved.

BOX 34-4 NURSING STORY

A Holistic Approach to Health

At the Integrative Medicine clinic, you are the nurse responsible for completing initial assessments and for counselling and advising new patients about complementary and alternative therapies during their first visit. Today, you meet Mrs. L., a 48-year-old woman, who is employed as a teacher. She has come to the clinic after multiple unsuccessful attempts to lose weight. Her current body mass index (BMI) is 32, which indicates obesity. She decided to visit the clinic after discovering that her latest serum glucose and cholesterol levels are elevated. She is considering gastric bypass surgery for permanent weight loss. Her primary reason for visiting the clinic is to learn what she can do to lose weight and to gain control of her health without undergoing a surgical intervention.

Key Points

Past history: Mother has hypertension and diabetes.

Social history: Relationships with her children and husband are strong. She attends church regularly and feels strongly connected to her faith.

Medications: She takes many herbal remedies and supplements for weight loss.

Attitude toward health: She cries during the interview and expresses anger about her perceived inability to take control of her health. She finds her occupation and family activities stressful; she has little time or energy left at the end of the day.

Approaches

First, ask some important questions. What is the patient's medical diagnosis? Is it correct? Could other medical problems be contributing

to her obesity? Have all the conventional medical therapies been thoroughly explored or considered? Has she discussed with her primary health care provider any other treatment plans? It is important to explore the patient's attitude, frame of mind, coping strategies, support systems, and goals. You also need to assess safer alternatives for achieving weight loss and her willingness to participate in them. One key element in her social history is her strong relationships with her family members and her faith. She will need to connect with those support systems to meet her weight loss goals within the larger context of improving the family's nutrition and health. Together with Mrs. L., you can explore practical steps that her family can take to help her meet her weight loss goals, such as purchasing groceries, planning and contributing to the preparation of healthy meals, and making time to exercise regularly. These elements must be combined with realistic weight loss guidelines, including a structured follow-up. Review the herbal and dietary supplements she uses and emphasize the importance of sharing this information with her primary health care provider to determine whether the supplements are beneficial or harmful to her health. You have a good opportunity to inform Mrs. L. about how to choose her supplements wisely. In developing her plan of care, create a realistic weight loss program that combines the benefits of exercise and other mind-body therapies, including journal writing, guided imagery with visualization, meditation (e.g., through a prayer group at her church); other helpful resources might include appropriate self-help books, weight loss and recipe books, and Web site resources that can provide her with more insight and information into the psychological, physical, and lifestyle challenges associated with losing weight effectively and permanently.

Relaxation Therapy

People are exposed to stressful situations in everyday life that evoke the **stress response** (see Chapter 29). The biochemical functions of major organ systems are modulated by the mind. Thoughts and feelings influence the production of chemicals (i.e., neurotransmitters, neurohormones, and peptides) that circulate in the body and convey messages to various body systems. Physiologically, the stress response can cause increased heart, respiratory, and metabolism rates; tightened muscles; and a general sense of foreboding, fear, nervousness, irritability, and negative mood. Other physiological responses include elevated blood pressure, dilated pupils, stronger cardiac contractions, and increased levels of blood glucose, serum cholesterol, circulating free fatty acids, and triglycerides. Although these responses effectively prepare a person for short-term stress, long-term stress can cause structural damage and chronic illness, such as angina, tension headaches, cardiac arrhythmias, pain, and ulcers (Dossey & Keegan, 2013).

Relaxation is a state of overall decreased cognitive, physiological, and behavioural arousal. The process of relaxation reduces the neural impulses sent to the brain, thus decreasing the brain's activity. Relaxation is characterized by decreases in heart and respiratory rates, blood pressure, and oxygen consumption and increases in muscle relaxation and alpha-wave brain activity. Relaxation can be achieved by using a variety of techniques that incorporate a repetitive mental focus and the adoption of a calm, peaceful attitude (Benson, 1975). Teaching strategies for relaxation are listed in Box 34-5.

Relaxation helps individuals develop cognitive skills to reduce negative responses to situations. Cognitive skills

include focus (the ability to identify, differentiate, and return attention to simple stimuli for an extended period), passivity (the ability to stop unnecessary goal-directed and analytical activity), and receptivity (the ability to tolerate and accept experiences that may be uncertain, unfamiliar, or paradoxical). By practising relaxation therapy, the patient learns to monitor and consciously release tension.

Progressive relaxation involves teaching individuals to effectively rest and to reduce their physical tension. The patient learns to detect subtle localized sensations of muscle tension in one muscle group (e.g., the forearm muscle). In addition, the patient learns to differentiate between high-intensity tension (strong fist clenching) and subtle tension (Dossey & Keegan, 2013). Progressive relaxation is then practised using different muscle groups. One active progressive relaxation technique involves the use of slow, deep abdominal breathing while tightening and relaxing an ordered succession of muscle groups. When guiding a patient, you may choose to begin with the muscles in the face, followed by the muscles in the arms, hands, abdomen, legs, and feet.

Passive relaxation involves teaching individuals to relax muscle groups without first actively contracting the muscles. One passive relaxation technique incorporates slow, abdominal breathing exercises with imagining warmth and relaxation flowing through specific muscle groups; muscle tension is then released during expiration. Passive relaxation is useful for patients who find that active muscle contracting leads to discomfort or exhaustion.

Clinical Applications of Relaxation Therapy. Relaxation techniques can lower heart rate and blood pressure,

BOX 34-5 PATIENT TEACHING

Relaxation

Objective

- The patient will demonstrate decreased anxiety, tension, and other manifestations of the stress response as a result of the relaxation intervention.

Teaching Strategies

Meditation and Rhythmic Breathing (Eliciting the Relaxation Response)

- Provide a quiet environment.
- Help the patient to a comfortable position, either seated or lying on the back. Have the patient remain as still as possible and encourage movement only if necessary to remain comfortable.
- Instruct the patient to close the eyes and to maintain a receptive attitude: for example, by repeating silently, "Nothing is more important for me to do for the next 15 minutes" or "What will be, will be."
- Instruct the patient to breathe in and out, slowly and deeply, by using the abdominal muscles and keeping the chest still.
- At the beginning of every exhalation, have patient repeat the number "1" silently in his or her mind. Continue for a period of meditation.
- Explain that when the mind wanders, the patient should acknowledge this and refocus attention by again slowly counting on the exhalation.
- Have the patient practise for 5, 10, 15, or 20 minutes per session. Practise daily for at least one session.

Progressive Relaxation

- Follow steps 1, 2, 3, and 4 of meditation and rhythmic breathing.
- When the patient is breathing slowly and comfortably, instruct the patient to tighten and relax an ordered succession of muscle groups, tensing them and then relaxing them.
- Instruct the patient to tense and then relax the calves, then the knees, and so on.

Relaxation by Sensory Pacing

- Follow steps 1, 2, 3, and 4 of meditation and rhythmic breathing.
- Instruct the patient to slowly repeat and finish each of the following sentences, either in a low voice or silently:
Now I am aware of seeing ...
Now I am aware of feeling ...
Now I am aware of hearing ...
- Instruct the patient to repeat and complete each sentence four times, then three times, then twice, and finally once.

Relaxation by Colour Exchange

- Follow steps 1, 2, 3, and 4 of meditation and rhythmic breathing.
- Instruct the patient to notice any tension, tightness, aches, or pains in the body and to give that sensation the first colour that comes to mind.
- Instruct the patient to breathe in pure white light from the universe and to send the light to a tense or painful place in the body, letting the white light surround the colour of the discomfort.
- Instruct the patient to exhale the colour of the discomfort and let the white light take its place.
- Instruct the patient to continue breathing in the white light and exhaling the colour of the discomfort, allowing the white light to fill the entire body and bring about a sense of peace, well-being, and energy.

Modified Autogenic Relaxation

- Follow steps 1, 2, 3, and 4 of meditation and rhythmic breathing.
- Instruct the patient to repeat each of the following phrases silently four times, saying the first part of the phrases while inhaling for 2 to 3 seconds, holding the breath for 2 to 3 seconds, then saying the last part of the phrases while exhaling for 2 to 3 seconds.

Breathing in

I am
My arms and legs
My heartbeat
My breathing
My abdomen
My forehead
My mind

Breathing out

relaxed.
are heavy and warm.
is calm and regular.
is free and easy.
is loose and warm.
is cool.
is quiet and still.

Relaxing With Music

- Ask the patient to select pleasing, slow, quiet music
- Instruct the patient to find a comfortable position (either sitting or lying down but with arms and legs uncrossed) and to close the eyes and listen to the music.
- Instruct the patient to imagine floating or drifting with the music.

Evaluation

- Assess the patient's vital signs, particularly the respiratory pattern.
- Ask the patient to describe the level of tension or uneasiness felt.
- Observe the patient for the presence of behaviours that display anxiety.

decrease muscle tension, improve perceived well-being, and reduce symptom distress in individuals experiencing a variety of situations (e.g., complications from medical treatment or grieving the loss of a significant other) (Hui et al., 2006; Kaushik et al., 2006). The type of relaxation intervention should be matched to the individual's functional status, the energy expenditure of the relaxation technique, and the motivation of the individual for frequent practice.

Relaxation therapy, either alone or in combination with deep breathing, imagery, yoga (Figure 34-5), and music, has been shown to reduce pain (Gustavsson & von Koch, 2006; Medlicott & Harris, 2006; Norrbrink et al., 2006), alleviate tension headaches (Kanji et al., 2006), and help to diminish anxiety related to HIV (Kemppainen et al., 2006). The practice of relaxation techniques also facilitates burn care (de Jong & Gambel, 2006), helps patients deal with post-traumatic stress (Stapleton et al., 2006), and improves cognition in healthy

aging adults (Galvin et al., 2006). More studies, however, are needed to validate the effects of relaxation therapy. For example, studies could test other variables or activities that may also lead to both reduced physiological activity and lower levels of pain to determine whether an individual's improved response is due to the relaxation therapy alone. Such variables may include a healthy support network, a positive attitude that includes the use of humour, and other behavioural therapies, such as yoga and tai chi.

Relaxation therapy is a valuable technique because it enables individuals to exert some control over their lives. The practice of relaxation techniques may help patients to experience a decreased feeling of helplessness and a more positive psychological state overall, thereby helping them to regard their situation less negatively.

Limitations of Relaxation Therapy. Some patients who use relaxation therapy have reported fearing a loss of

Figure 34-5 Yoga focuses on muscles, posture, breathing, and consciousness.

control, feeling like they are floating, and experiencing anxiety related to these feelings. Relaxation training teaches individuals to distinguish between low and high levels of muscle tension. During the first months of training, when learning to focus on sensations and tension, some patients report increased sensitivity in detecting muscle tension. Usually these feelings abate with training; however, you should monitor patients for worsening symptoms and for the development of new symptoms (Dossey & Keegan, 2013).

When choosing which relaxation technique to use, consider the physiological and psychological status of the patient. Patients with advanced diseases, such as cancer, may seek relaxation training to reduce their stress response; however, techniques such as active progressive relaxation training require a moderate expenditure of energy, which can amplify a person's existing fatigue and limit the ability to complete individual relaxation sessions and practice. Therefore, active progressive relaxation is not appropriate for patients with advanced disease or with decreased energy reserves. For these individuals, passive relaxation or imagery is more appropriate.

Meditation and Breathing

Meditation is any activity that limits stimulus input by directing the attention to a single unchanging or repetitive stimulus (Rakel & Faass, 2006). Meditation is a general term that refers to a range of practices that relax the body and still the mind. The root word, *meditari*, means "to consider." In 1975, Dr. Herbert Benson's book *The Relaxation Response* drew the attention of Western health care practitioners to the physical and psychological benefits of relaxation. As Benson noted, the components of meditation are simple: a quiet space, a comfortable position, a receptive attitude, and a focus of attention. He described meditation as a process that anyone can use to calm down, to cope with stress, and, for those with spiritual inclinations, to feel at one with God or the universe. Meditation is compatible with most religious traditions and can be practised alone or in groups. Most meditation techniques involve slow, relaxed, deep, usually abdominal, breathing (see Box 34-5). Meditation evokes a restful state, lowers oxygen consumption, reduces respiratory and heart rates, and decreases anxiety.

Clinical Applications of Meditation. Many conditions are indications for meditation (Box 34-6). Evidence has shown that meditation improves breathing patterns in patients with asthma, manages stress-related illnesses, and lowers blood pressure (Merkes, 2010; Paul-Labrador et al., 2006).

BOX 34-6 Indications for Meditation

- Anxiety or tension
- Chronic bereavement
- Chronic fatigue syndrome
- Chronic pain
- Drug abuse, alcohol abuse, tobacco use
- Hypertension
- Irritability
- Low self-esteem; self-blame
- Mild depression
- Psychophysiological disorders
- Sleep disorders

AIDS patients use meditation to reduce stress and anxiety (Brazier et al., 2006). Also benefiting from meditation are cancer patients (Zaza et al., 2005) and individuals with depression (Brown & Gerbarg, 2005). Battered women benefit from a meditation practice (Kane, 2006), as do those who have chronic low back pain (Mehling et al., 2005). Meditation also increases a person's productivity and sense of self, improves mood, and reduces irritability (Dossey & Keegan, 2013).

When considering the use of meditation for a patient, consider the patient's degree of self-discipline, although meditation actually requires less self-discipline than most other behavioural therapies.

Limitations of Meditation. Although meditation can have numerous physiological and psychological benefits, it may be contraindicated in some patients. For example, a patient with a strong fear of losing control may perceive meditation as a form of mind control and thus be resistant to learning the technique. Some patients respond well to meditation and require shorter sessions than the typical 15 to 20 minutes.

Meditation can also augment the effects of certain drugs. For example, individuals taking medications to treat hypertension, overactive or underactive thyroid glands, depression, or anxiety should be monitored. The prolonged practice of meditation techniques may, in some cases, lead to the reduced need for certain medications, and some doses of medications may need to be adjusted. Individuals learning meditation, therefore, should be monitored closely for physiological changes with respect to their medications.

Imagery

Imagery or visualization techniques, which are frequently used with relaxation training, help create mental images to stimulate physical changes, improve perceived well-being, and enhance self-awareness. Imagery can be either self-directed or guided by a practitioner (Dossey & Keegan, 2013). For example, the patient may be directed to begin slow, abdominal breathing while focusing on the rhythm of the breath. The patient is then guided to visualize ocean waves washing onto a shore with each inhalation, then receding with each exhalation. Next, the patient is encouraged to notice the smells, sounds, and temperatures that he or she is experiencing. As the session progresses, the patient may be instructed to visualize warmth entering the body during inspiration and tension leaving the body during expiration. Imagery scenarios can be individualized for each patient or left to the patient to develop.

Imagery can evoke powerful psychophysiological responses, such as alterations in the immune function (Fontaine, 2005). Many imagery techniques involve visual imagery, but they can also include the auditory, gustatory, and olfactory senses. For

BOX 34-7 PATIENT TEACHING

Creative Visualization

Objective

The patient will demonstrate skills in creative visualization.

Teaching Strategies

- Set goals that can be accomplished because confidence and increased self-esteem are achieved through success.
- Create clear images described in the present tense (e.g., imagine you are floating on a soft, white cloud).
- Frequently visualize the image. Visualization should be practised throughout the day but especially upon awakening or before sleep, when the mind is usually more relaxed.
- While focusing on the image, repeat encouraging statements, such as positive affirmations to alleviate doubts about the ability to achieve goals.

Evaluation

- Observe the patient for anxiety.
- Ask the patient whether the experience was helpful.
- Ask the patient whether he or she uses positive self-dialogue with visualization (e.g., "I am feeling stronger").
- Note whether the patient reports images of desired health habits, desired feelings, and desires for healing.
- Note whether the patient reports improved coping with daily stressors.

Figure 34-6 Biofeedback monitoring. Electrodes are placed on the frontalis and trapezius muscles and on the fingers of the left hand. Pneumograph measurements are also made.

example, visualizing a lemon being sliced in half and squeezing the lemon juice under the tongue has been observed to produce increased salivation as effectively as the actual event. People typically respond to their environment according to the way they perceive it and according to their own visualizations and expectations. Therefore, individuals can learn to self-regulate their visualization experiences by selecting appropriate visualizations and expectations (Dossey & Keegan, 2013).

Creative visualization as first described by Gawain (2002) is a form of self-directed imagery that is based on the principle of mind-body connectivity (i.e., every mental image leads to physical or emotional responses). Patient teaching strategies for creative visualization are listed in Box 34-7.

Clinical Applications of Imagery. Imagery is used to control or relieve pain, to achieve calmness and serenity, and to visualize cancer cells being destroyed by immune system cells. Imagery is also used in the treatment of chronic conditions, such as asthma, hypertension, functional urinary disorders, menstrual and premenstrual syndromes, rheumatoid arthritis, and gastrointestinal disorders, such as irritable bowel syndrome (Dossey & Keegan, 2013; Fontaine, 2005).

Limitations of Imagery. Imagery has few side effects; however, it is probably one of the least clearly defined interventions and can range from being highly structured to consisting of spontaneous daydreams (Rakel & Faass, 2006).

Training-Specific Therapies

Training-specific therapies are CAM treatments that may be administered by nurses but only after the completion of a specific course of study and training. A nurse must have a certification, degree, or licence beyond a registered nursing degree to administer most of these therapies. Several training-specific therapies are recognized as effective and are

recommended by Western health care practitioners (e.g., biofeedback and therapeutic touch). Many other therapies have not yet been studied in a systematic way to establish effectiveness. Many of these unproven techniques are very popular in our society and are used by many persons from other cultures who now live in Canada. Many therapies have positive effects, but some have negative effects, too. Some may have harmful results when used with standard Western medical therapies. Therefore, you need to acquire knowledge of such treatments and to be aware of their possible harmful interactions.

Biofeedback

Biofeedback techniques are frequently used in addition to relaxation interventions to assist individuals in learning how to control specific autonomic nervous system responses. **Biofeedback** is a group of therapeutic procedures that use electronic or electromechanical instruments to measure, process, and provide information about neuromuscular and autonomic nervous system activity (Figure 34-6). This information, or feedback, is provided in physical, physiological, auditory, and visual measurements through a pneumograph. For example, patients may hear a sound if their pulse rate or blood pressure increases out of their therapeutic zone. Biofeedback practitioners help patients to develop awareness of and voluntary control over physiological responses (Rakel & Faass, 2006).

Biofeedback is considered to complement traditional relaxation programs because it can immediately demonstrate to patients their ability to control some physiological responses. Biofeedback also helps individuals to focus on and monitor responses in specific body parts. By providing immediate feedback for the stress relaxation behaviours that work most effectively, patients learn to control the physiological functions that are most difficult to control. Eventually, the patient will be aware of positive physiological changes without the need for instrument feedback. Biofeedback demonstrates to the patient the relationships between thoughts, feelings, and physiological responses.

Clinical Applications of Biofeedback. Biofeedback has numerous applications. It has successfully treated migraine headaches (Damen et al., 2006), other pain (Breuhl & Chung, 2006), stroke (Cristea et al., 2006), and a variety of gastrointestinal and urinary tract disorders (Chiarioni et al., 2005).

One of the most critical components of any behavioural program is adherence to the treatment regimen. Patients who are compliant with appointments, practice times, and goal setting tend to be the most successful.

Limitations of Biofeedback. Although biofeedback has demonstrated effectiveness in a number of patient populations, several precautions should be noted. During relaxation therapy and biofeedback sessions, repressed emotions or feelings may emerge, and patients may find they cannot cope with these emotions alone. For this reason, practitioners should be trained in traditional psychological methods or be able to refer patients to qualified professionals.

Therapeutic Touch

Therapeutic touch (TT) is a training-specific therapy that was developed in the 1970s by a nurse, Dr. Dolores Krieger. Although the philosophical and religious assumptions of TT differ from those of other Eastern healing modalities, both practices involve trained practitioners who attempt to direct their own balanced energies in an intentional and motivated manner toward the patient (Krieger et al., 1979).

TT consists of the practitioner's hands being placed either on or close to a person's body (Figure 34-7). The practitioner scans the patient's body and diagnoses areas of accumulated tensions. The practitioner then attempts to redirect these energies to bring the person's energy back into balance (Krieger, 1975; Krieger et al., 1979).

TT consists of five phases: centring, assessment, unruffling, treatment, and evaluation. Centring is the process whereby the practitioner becomes aware and fully present during the entire treatment. The next phase, assessment of the patient, involves the practitioner moving his or her hands (roughly 5 to 15 cm from the body) in a rhythmic and symmetrical movement from the head to the toes. During this phase, the practitioner notices the quality of **energy flow** and detects accumulations of energy. Physiological indicators of energy imbalance are perceived as congestion, pressure, warmth, coolness, blockage, pulling or drawing, or static or tingling (Krieger, 1975). During the third phase, the practitioner "unruffles" the energy flow or facilitates the symmetrical and rhythmical flow of energy through the body with long downward strokes over the energy field located over the entire body. This rebalancing of energy is achieved either by the practitioner touching the body or by

maintaining the hands in a position a few centimetres away from the body. The final phase consists of an evaluation of the patient and a reassessment of the energy field. If rebalance is achieved, the practitioner detects a more symmetrical, freely flowing energy field (Krieger et al., 1979).

Clinical Applications of Therapeutic Touch. Early studies found that TT was able to increase hemoglobin levels in several patients (Krieger, 1975; Krieger et al., 1979). This same positive result was found in a recent study (Movaffaghi et al., 2006). Other studies have found that TT reduced headache pain, improved the mood of bereaved adults, and reduced anxiety levels in hospitalized patients with cardiovascular disease (Krieger, 1975; Krieger et al., 1979).

Limitations of Therapeutic Touch. Although some studies have demonstrated that TT produces positive outcomes, others have not. TT may be contraindicated in certain patient populations. For example, patients who are sensitive to human interaction and touch (e.g., individuals who have been physically abused or have psychiatric disorders) may misinterpret the intent of the treatment and may feel threatened and anxious. Other patients who are sensitive to energy repatterning may also need to avoid TT. These patients include premature infants, newborns, children, pregnant women, older or debilitated people, and patients who are in critical, unstable conditions (Fontaine, 2005).

Chiropractic Therapy

Chiropractic therapy was developed in 1895 and has become the third-largest independently practised health profession in the Western world (Rakel & Faass, 2006). Chiropractors graduate from well-established preparatory programs similar to medical schools. The central tenet of the chiropractic profession is spinal manipulation directed at specific joints. Manipulation is defined as the forceful passive movement of a joint beyond its active limit of motion. Practitioners use either their hands or an instrument to manipulate the spine. Chiropractic therapy is considered a holistic therapy that does not typically use drugs or surgery.

The basic principles of chiropractic therapy incorporate the idea that human beings have an innate healing potential; harnessing this potential is the goal of this healing profession. Chiropractic therapy promotes both a natural diet and regular exercise as essential components for the body to function properly (Fontaine, 2005).

Clinical Applications of Chiropractic Therapy. The basic goals of chiropractic therapy focus on restoring the body's structural and functional imbalances that may result in pain. One of the major structural distortions that chiropractors treat is vertebral subluxation, in which joint mobility is decreased due to slight changes in the position of the articulating bones. A more severe form of subluxation, called fixation, exists when joint motion is restricted. Chiropractic interventions treat musculoskeletal abnormalities, headaches, dysmenorrhea, disorders of blood pressure, vertigo, tinnitus, and visual disorders (Rakel & Faass, 2006).

Limitations of Chiropractic Therapy. Several diseases or joint conditions should not be treated by manipulation. If a malignancy is suspected or determined through diagnostic testing, the patient should be referred to a medical physician for further evaluation and treatment. Bone and joint infections also require pharmaceutical or surgical intervention, and the structural integrity of the bone may be compromised if excessive force is used. Contraindications for chiropractic

Figure 34-7 In therapeutic touch, the practitioner's own energy is directed to help or heal another person.

▶ TABLE 34-2

Three Causes of Disease According to Traditional Chinese Medicine

Cause of Disease

External causes, or “the six evils”
Internal causes, or internal damage by seven effects
Nonexternal, noninternal causes

Influences

Wind, cold, fire, damp, summer heat, dryness
Joy, anger, anxiety, thought, sorrow, fear, fright
Dietary irregularities, excessive sexual activity, fatigue, trauma, parasites

therapy include acute myelopathy, fractures, dislocations, rheumatoid arthritis, and osteoporosis. Severe complications secondary to neck and spine manipulation are rare; however, some research suggests avoiding this type of manipulation on infants and children (Vohra et al., 2007).

Traditional Chinese Medicine

Traditional Chinese medicine (TCM) comprises several healing modalities, including herbal remedies, acupuncture, moxibustion, diet, exercise, and meditation. TCM is several thousand years old. A major concept in Chinese medicine is the **yin and yang**, which represent opposing, yet complementary, phenomena that exist in a state of dynamic equilibrium. Examples of yin and yang are night and day, hot and cold, and shady and sunny. Yin represents shade, cold, and inhibition, whereas yang represents fire, light, and excitement. Yin also represents the inner part of the body, specifically the viscera, liver, heart, spleen, lungs, and kidneys, whereas yang represents the outer part, specifically the bowels, stomach, and bladder. According to TCM, when an imbalance occurs in these paired opposites, disease can emerge (Fontaine, 2005).

Qi (pronounced *chee*) is defined as the body’s vital energy. Disease is classified into three major categories: external causes, internal causes, and neither internal nor external causes (Table 34-2). Regardless of the cause, when yin and yang are out of balance, the movement of qi is altered. The body has several forms of qi that directly influence its physiological functions and help maintain homeostasis.

Channels of energy run in regular patterns throughout the body and over its surface. These channels, called **meridians**, are like rivers flowing through the body. An obstruction of these meridians functions like a dam, by backing up the flow in one part of the body and restricting the flow in other parts, eventually leading to disease. Located along the channels are **acupoints**, or holes through which qi can be influenced by the insertion of needles, a process known as **acupuncture**.

Another important component of Chinese medicine involves five elements: earth, metal, water, wood, and fire. Various health phenomena are organized according to these elements and interact with each other. In Chinese medicine, outward manifestations reflect the internal environment. Two primary areas are assessed in Chinese medicine: the tongue and several pulses. The colour, shape, and coating of the tongue reflect the general condition of the internal organs. The pulses provide information about the condition and balance of qi, blood, yin and yang, and internal organs (Fontaine, 2005).

Acupuncture

Acupuncture is a method of stimulating certain points (acupoints) on the body by the insertion of special needles to

Figure 34-8 Acupuncture involves the insertion of special needles to regulate the flow of energy.

modify the perception of pain, normalize physiological functions, or treat or prevent disease (Figure 34-8). Acupuncture is used to regulate the flow of qi. According to Chinese traditional medicine, acupuncture needles unblock obstructed energy and re-establish the flow of qi through the meridians, thereby stimulating and activating the body’s self-healing abilities. The effects of the acupuncture needles may be enhanced by applying heat or weak electrical currents to the needles (Fontaine, 2005).

Clinical Applications of Acupuncture. Acupuncture is the primary treatment used by practitioners of Chinese medicine. Many allopathic physicians and health care providers are also trained and certified in acupuncture.

Acupuncture is used to treat low back pain, myofascial pain, headaches, tennis elbow, osteoarthritis, whiplash, and musculoskeletal sprains. Other problems that have been successfully treated are sinusitis, gastrointestinal disorders, menstrual symptoms, neurological disorders, chronic pulmonary diseases (including asthma), hypertension, smoking and other addictions, and clinical depression (Rakel & Faass, 2006).

Limitations of Acupuncture. Acupuncture is considered a safe therapy when the practitioner has successfully completed the appropriate training and uses sterilized needles. Although complications have been noted, they are rare if appropriate steps are taken to ensure the safety of the equipment and the patient. These complications include the puncture of an internal organ, bleeding, fainting, seizures, miscarriage, post-treatment drowsiness, and infections from contaminated or broken needles or from needles that have been left in place for an extended length of time.

Acupuncture should be used with caution in pregnant patients and patients who have a history of seizures, are hepatitis carriers, or are infected with HIV. Acupuncture treatment is contraindicated in people with bleeding disorders, thrombocytopenia, or skin infections.

Electroacupuncture should be avoided in people who have pacemakers, are pregnant, or have cardiac arrhythmias or epilepsy (Fontaine, 2005).

Role of Nutrition in Disease Prevention and Health Promotion

A growing body of scientific evidence over the past few decades has been exploring the relationship between **nutrition** and its preventive effect on disease. Substantial evidence from

epidemiological studies indicates that the relationship between nutrition and cancer, diabetes, and cardiovascular disease is often directly linked to lifestyle and nutritional choices.

Current scientific research relates diet and nutrition to cancer risk (Berkow et al., 2007; Chan et al., 2006; Webb & McCullough, 2005). The research findings are conclusive enough for some investigators to suggest that further research should focus on developing protective nutritional strategies against cancer, especially because of people's increasing exposure to environmental carcinogenic agents and because of the aging of populations worldwide (Dinkova-Kostova, 2007; Thorogood et al., 2007). Canadians typically consume a diet lacking in foods of plant origin (fruits and vegetables) and high in fat, including refined and processed foods with little or no nutrient value. Consequently, rates of obesity are rising in our country, particularly for young children. The prevalence of diseases such as type 2 diabetes, which previously was rarely seen in young children, is now increasing in this population.

Studies show that increased intake of whole grains and dietary fibre is inversely associated with insulin resistance and type 2 diabetes (Li & Uppal, 2010). Coronary heart disease is a leading cause of death and is related to lifestyle choices, including overeating, inactivity, and poor diet choices. The value of nutrition has become clear, evidenced by studies that have found strong correlations between what researchers identify as Western diseases (e.g., coronary artery disease, obesity, unhealthy dietary habits) (Berkow et al., 2007). Research has shown that the primarily plant-based Mediterranean diet, which is rich in fruits, vegetables, and fish, reduces the risk of heart disease. Dean Ornish et al. (1998) determined that intensive lifestyle and dietary changes could, in fact, reverse coronary artery disease. Research is ongoing, but numerous studies indicate that attention to diet and to factors such as weight and exercise has been proven to reduce cancer risk. In addition, current research is examining the complex relationships between specific food components and their health effects. Whole foods (foods that are raw, unrefined, and minimally processed) provide more nutrients than can be obtained from supplements. A single fruit or vegetable contains many protective chemicals and nutrients that cannot be sourced from a supplement alone. These plant chemicals, commonly called *phytochemicals*, work together to provide a better defence against disease. Phytochemicals provide pigment and flavour; they give garlic its pungent taste and give fruits and vegetables their bright and varied colours (Bragdon & Scroggs, 2006).

Phytochemicals are antioxidants, which are compounds that protect cells from damage. Antioxidants destroy free radicals, which are chemicals that are produced when the body uses oxygen. Free radicals can damage cells, thereby leading to the mutations that cause cancer. Several phytochemicals are being studied to determine how they influence the cancer process (Bragdon & Scroggs, 2006; Milner, 2006).

The Canadian Cancer Society (2011) addresses some key dietary sources of phytochemicals that are optimal for health and disease prevention and advise choosing a food from each colour group every day. Colour groups and some examples of their foods include dark green and orange (carrots, spinach, oranges); red and blue or purple (beets, red peppers, blueberries); and white, brown, and tan (cauliflower, garlic, bananas). In association with the Canadian Cancer Society, Beliveau and Gingras (2006) have written a book that addresses how a healthy diet can prevent disease and offers recipes geared toward preventing cancer.

Despite the lack of conclusive data that dietary changes can prevent cancer, sufficient evidence exists to suggest that cancer risk can be reduced by eating more fruit, vegetables, and whole foods. Cancer is a complex group of diseases with many causes not related to diet alone but to a combination of individual and general risk factors. Because of the relationship of diet to many other lifestyle diseases, the best approach to nutrition may be to focus on a well-balanced, whole-food approach rich in disease-fighting phytochemicals.

Herbal Therapies

An estimated 25,000 plant species are used medicinally throughout the world. **Herbal therapy** is the oldest form of medicine; archeological evidence suggests that Neanderthals used herbal remedies 60,000 years ago. Herbal therapy was widespread for thousands of years, but its popularity declined with the development of modern scientific medicine in the early eighteenth century. However, because approximately 80% of the world's population lives in developing countries, herbal medicine constitutes a prominent approach to health care worldwide. In countries that use predominantly allopathic medicine, an increased interest in herbal medicine has developed from consumer interest in natural foods and growing concern about the complications and limitations of scientific medicine (Fontaine, 2005).

Herbal substances are extracted from plants, animals, and minerals. The active ingredients are prepared in tinctures or extracts, elixirs, syrups, capsules, pills, tablets, lozenges, powders, ointments or creams, drops, and suppositories. Many people think, incorrectly, that because herbs are natural plants, they cannot cause harm or side effects. As with other medications, some herbal substances contain powerful chemicals and should be examined for interaction and compatibility with other prescribed or unprescribed substances. As well, many herbs are sold with claims that they can "cure" certain ailments when their efficacy has not been determined through clinical trials. In a study on herbal remedies for psoriasis (Steele et al., 2007), the magnitude of information on the Internet (more than 1 million sites offered by Yahoo! versus 31 articles found in the medical literature) illustrates the lack of scientific evidence to support the many uses of herbal remedies. Herbs are, in general, classified as beneficial, harmful, or neutral, in which case they have no effects on the specific ailment.

The philosophy of herbal therapy differs from the philosophy of conventional drug therapy. The goal of herbal therapy is to restore balance within the individual by facilitating the self-healing ability. Drug therapy, on the other hand, is aimed at the treatment of a specific disease or symptoms. Herbal therapy is also prescribed on an individual basis with unique herbal concoctions tailored for each person. Many herbal medicines are sold as food, food supplements, or natural health products in health food stores and through private companies.

According to the Canadian *Food and Drugs Act*, all drugs must be proven safe and effective before being sold to the public. A Health Canada (2005) survey revealed that of 2004 persons surveyed, 71% had used a natural health product.

Health Canada regulates all over-the-counter **natural health products** (NHPs) for safety, effectiveness, and quality. NHPs are considered to be any product derived from a plant, animal, or microorganism (e.g., herbs, probiotics, essential fatty acids) and vitamins, minerals, and homeopathics that are, in the words of the Act, used to "diagnose, treat, prevent disease; restore or correct function, maintain or promote health." These

regulations include good manufacturing practices and guidelines for obtaining a product licence. NHPs that have been approved for sale under the new regulations have been assigned a Drug Identification Number (DIN; DIN-HM for homeopathic medicines) or natural product number (NPN). These numbers certify that the product has passed a review of its formulation, labelling, and instructions for use. Health Canada advises Canadians to use only health products that carry a DIN, DIN-HM, or NPN on the label.

Clinical Applications of Natural Health Products (NHPs)

Numerous natural health products have been determined to be safe and effective for a variety of conditions (Table 34-3).

Milk thistle, for example, can effectively treat certain liver and gallbladder conditions; its antioxidant properties are believed to protect the liver and facilitate regeneration of liver cells. St. John's wort has been found to be effective as a tricyclic antidepressant agent and more effective than placebo (Linde et al., 2008).

Limitations of NHPs. Although NHPs have been shown to provide beneficial effects for a variety of conditions, a number of problems may exist. Concentrations of active ingredients can vary considerably, and contamination may occur with prescription medications and other herbs or chemicals, including pesticides and heavy metals. Some herbs have also been found to contain toxic products that can cause cancer. Comfrey, for example, has been used for its wound-healing

► **TABLE 34-3** Natural Health Products in Common Use and Considered Safe

Common Name	Effects	Indications*	Warnings†	Other
Black cohosh	Estrogen-like effects	Menopausal hot flashes Premenstrual syndrome	Significant estrogenic activity has not been found but not recommended if patient has a history of breast cancer	Is promising for the relief of moderate hot flashes related to menopause
Chamomile (German or Hungarian)	Topically: Anti-inflammatory Orally: Anti-inflammatory, antiestrogenic effects	Chemotherapy-induced mucositis Dyspepsia Colic Inflammatory conditions Insomnia Menstrual disorders	Contraindicated if allergies to the daisy family May potentiate the effect of anticoagulants and CNS depressants	Avoid confusion with Roman chamomile
Echinacea	Topically: Anaesthetic and anti-inflammatory, wound healing Orally: Stimulates the immune system	Upper respiratory infections Colds Urinary tract infections	Contraindicated in patients receiving cancer treatments and for people with autoimmune diseases, multiple sclerosis, tuberculosis, diabetes, asthma, leukemia, HIV/AIDS, lupus, or allergies to the daisy family Not to be used longer than 8 weeks	Chemical constituents differ among roots, leaves, and flowers
Evening primrose oil	Anti-inflammatory constituents omega-6 and gamma-linoleic acids	Mastalgia Atopic dermatitis Premenstrual syndrome (PMS) Menopausal hot flashes	Contraindicated in patients with seizure disorders Large doses may cause loose stools and abdominal pain	Studies have shown positive effects on relieving mastalgia (cyclic breast pain)
Fish oil	Omega-3 essential fatty acids are believed to have anti-inflammatory properties	Rheumatoid arthritis Rheumatoid arthritis Prevention of cardiovascular disease and cancer	Possible increase of INR with coumadin Avoid doses greater than 3 gm/day to avoid inhibiting blood coagulation Quality of product should be monitored for cancer-causing pollutants, such as dioxin and PCBs	Effective in reducing triglyceride levels The Mediterranean diet, which is rich in fish, has been associated with lower rates of cancers May improve overall cognitive functioning and behaviour in children with attention deficit-hyperactivity disorder (ADHD)

TABLE 34-3 Natural Health Products in Common Use and Considered Safe—cont'd

Common Name	Effects	Indications*	Warnings†	Other
Garlic	Major constituent allicin reduces oxidative stress and stimulates the immune system Inhibits platelet aggregation	Hypertension Cold and flu prevention Athlete's foot (topically)	May prolong bleeding time Possible interactions with anticoagulants Topical application may cause skin irritation	Supplementation not recommended for use during pregnancy due to its effect on bleeding time
Ginger	Antiemetic Antibiotic	Motion/morning sickness Nausea and vomiting Vertigo	May enhance the effects of coumadin, aspirin, and NSAIDs	Recent studies indicate no fetal harm when used for morning sickness
Ginkgo biloba	Contains flavonoids and organic acids that have anti-inflammatory/antioxidant effects Inhibits platelet-activating factor	Dementia Poor circulation Poor memory	Ingestion may increase the risk of serious bleeding, especially in patients taking anticoagulants or NSAIDs Can cause contact dermatitis High doses can cause seizures	Potential promise in enhancing cognitive functions in people with dementia and improving peripheral arterial disease
Glucosamine (Hydrochloride/sulphate)	Naturally occurring amino sugar that stimulates the synthesis of proteins responsible for cartilage growth and maintenance	Joint pain Osteoarthritis	May increase the anticoagulant effects of coumadin	Mounting evidence for pain reduction and disease-modifying effects in osteoarthritis
Milk thistle	Silymarin, the active constituent, is a potent inhibitor of tumour necrosis factor (TNF), which reduces toxicity to the liver and reduces inflammation	Chronic hepatitis Cirrhosis GI upset	Reports on significant decrease in fasting blood glucose in diabetics using conventional diabetic therapy	Do not confuse with Blessed Thistle Mixed evidence on effectiveness in managing hepatitis or cirrhosis
Saw palmetto	Androgen receptor blocker Anti-inflammatory	Benign prostatic hyperplasia (BPH) Urinary problems	Increased risk of bleeding if on anticoagulants	Evidence suggests that it provides mild to moderate improvement for urinary problems
St. John's wort	Inhibits reuptake of serotonin, dopamine, and norepinephrine neurotransmitters Wound healing (topical)	Depression Sedative Menopausal symptoms	Not appropriate for severe depression May enhance the effects of SSRIs and other antidepressants Significant interactions with many drugs and herbs Photosensitivity with chronic use	Studies support its use in treating mild to moderate depression
Valerian	Valepotriate constituents have sedative-hypnotic and smooth muscle effects	Muscle spasms Sleep disorders Restlessness	May cause headaches or gastrointestinal disturbances Patient must avoid using concurrently with other sedatives	Studies support its use in treating insomnia and improving sleep quality

INR, International normalized ratio; NSAIDs, nonsteroidal anti-inflammatory drugs; PCBs, polychlorinated biphenyls; SSRIs, selective serotonin reuptake inhibitors.

*Unless otherwise noted, these natural health products have not shown sufficient evidence to rate their effectiveness for all stated indications.

†Data do not support the use of these herbs in infants or children or during pregnancy or lactation.

properties; however, various species of comfrey contain highly carcinogenic pyrrolizidine alkaloids and have produced liver cancer in small animals. Other unsafe NHPs are listed in Table 34-4.

Not all companies follow strict quality-control and manufacturing guidelines, which set standards for acceptable levels

of pesticides, residual solvents, bacterial levels, and heavy metals.

For this reason, NHPs should be purchased only from reputable manufacturers (Box 34-8). In addition, labels on herbal products should include the scientific name of the botanical, the name and address of the manufacturer, the batch or lot

► TABLE 34-4 Unsafe Natural Health Products

Common Name	Uses	Comments
Aconite (Aconitum, Blue Monkshood Root)	Pain and inflammation (arthritis, gout, etc.)	Contains alkaloids toxic to the heart and CNS
Coltsfoot (British tobacco, Coughwort)	Bronchitis Asthma Sore throat	Most common type of severe herbal poisoning in Hong Kong Contains large number of hepatotoxic pyrrolizidine alkaloids that can cause cancer
Comfrey (Blackwort, Slippery root)	Wound healing Gastritis Cancer	Contains large number of toxic hepatotoxic pyrrolizidine alkaloids that can cause cancer
Country Mallow (Heartleaf, White Mallow)	Asthma Colds and nasal congestion	Contains ephedrine similar to the stimulant ephedra, which can cause heart attack and seizure (unauthorized for sale as an NHP by Health Canada)
Greater Celandine (Celandine, <i>Chelidonium herba</i>)	Dyspepsia Irritable bowel syndrome (IBS) Gastric cancer	Over a dozen reports of hepatitis in several oral preparations
Ephedra Ma Huang, herbal Ecstasy	Weight loss Athletic performance enhancer	Unsafe for people with hypertension, diabetes, or thyroid disease due to stimulant effects Many interactions with herbs and drugs Health Canada (2005) advisory against use of any product containing this substance Banned in United States (2004)
Kava	Anxiety and stress Sleep aid	Hepatotoxicity and liver failure Issues related to contaminants in product Health Canada (2010) advisory against use
Lobelia (Asthma Weed, Indian Tobacco)	Asthma Bronchitis Whooping cough	CNS overstimulation may cause tachycardia, hypotension, and possibly death
Yohimbe	Used to treat impotence, as an aphrodisiac	May cause kidney damage, cancer, hypertension, and cardiac conduction disorders

number, the date of manufacture, and the expiration date. If the product has been assessed by Health Canada for safety and effectiveness, it will also have a DIN-HM or NPN on its label.

Nursing Role in Complementary and Alternative Therapies

The integrative medicine approach is consistent with the nursing holistic approach. Indeed, many nurses already practise the use of simple touch. This therapy is an example of a holistic approach to care that includes a variety of practice modalities designed to promote the health and well-being of the patient. The use of these practice modalities is based on the assumption that nurses practise within the Scope of Practice, as defined by the Canadian Nurses Association (Canadian Holistic Nurses Association, 2008). As essential participants, nurses who provide CAM therapies must have the knowledge and skill necessary to provide care safely and ethically through self-study, certificate courses offered by community colleges, or study with expert practitioners. Nurses should understand provincial and territorial legislation regarding complementary therapies, practise within the scope of these laws, and be able to make appropriate recommendations about CAM therapies to allopathic primary care providers. Various nursing resources on CAM are available through the Canadian Holistic Nurses

Association. The College and Association of Registered Nurses of Alberta (2011) has developed a guide for registered nurses. These resources help you to understand your professional responsibilities, the ethics related to implementation and advisement of CAM, and the general implications for nurses.

You also need to keep abreast of the current research in the field of CAM therapy to provide accurate information to patients and other health care providers. For example, the Canadian Interdisciplinary Network for Complementary and Alternative Medicine Research has been created to foster excellence in CAM research (Andrews & Boon, 2005).

You should advise patients about the appropriate times to use conventional or CAM therapy. Patients often look to you for advice on the use of different therapies; therefore, you need to have knowledge of both the potential benefits and the risks associated with these therapies. For example, if a patient complains of right lower abdominal pain, nausea, and vomiting—signs of appendicitis—you should recommend an allopathic assessment. However, if the patient has a chronic gastrointestinal disorder and is diagnosed with irritable bowel syndrome, you may suggest the patient could benefit from relaxation therapy and herbal therapy. Because you work very closely with your patients, you are in a unique position to become familiar with patients' religious and cultural viewpoints. You may be able to determine which CAM therapies would be best suited to individual beliefs.

* BOX 34-8 FOCUS ON PRIMARY HEALTH CARE

Educating Patients About Purchasing Natural Health Products

Many people who buy NHPs are unaware of the lack of regulation regarding the manufacturing and sale of such products. It is difficult to make informed decisions when faced with hundreds of products. When patients choose to use NHPs, they should purchase these products only from reputable manufacturers to ensure safety, appropriate use, and response.

You can help patients make informed choices about NHPs by offering these guidelines:

- Avoid hype: Be wary of supplements that offer a “cure” or a “secret formula.”
- All product labels should indicate the following:
 - The scientific name of the botanical
 - The quantity, concentration, expiration date, and manufacturer's name
 - The purpose, dosage form, route of administration, and warnings of possible adverse reactions
 - The names of other key ingredients
 - The natural product number (NPN) or Drug Identification Number (DIN-HM), which indicates that Health Canada has reviewed its formulation

- Ensure the product is supported by published research. Avoid “multi-ingredient” formulations when possible; otherwise, determining potential reactions with other medicines will be difficult. Consumers often pay more for secondary products that may not be present in established therapeutic levels.
- Look for well-educated service staff who can answer consumers' questions.
- Be cautious about “mega” doses of anything: even excess ingestion of certain vitamins can be toxic.
- Be sceptical about cheap herbal remedies. Consumers must pay for the manufacturer's investments in ensuring quality and purity. Very inexpensive herbal products are often of inferior quality.
- NHPs used for weight loss, body building, sleep problems, and diabetes have become a worldwide problem due to the addition of prescription and nonprescription drugs. Purchasing unauthorized NHPs through the Internet may increase your risks for unsafe products.

You should encourage patients to inform all caregivers, including other health care providers, about the medications and therapies they receive. In particular, complete information about the use of NHPs should be added to the medical record to prevent potential drug and herb interactions.

❖ KEY CONCEPTS

- Complementary therapy is used in conjunction with allopathic medicine, whereas alternative therapy is generally used without the addition of conventional health care methods.
- Integrative medicine uses a multidisciplinary (both allopathic and complementary) treatment approach.
- Stress is an adaptive response that allows individuals to react to demanding situations.
- Chronic stress may be maladaptive, thereby leading to chronic muscle tension and changes in mood and immunity.
- Relaxation is a beneficial state characterized by improved mood, relaxed muscle tension, lowered blood pressure, and slower pulse and respiratory rates.
- To be most effective and to have prolonged beneficial outcomes, complementary and alternative medicine therapies require the patient's commitment and regular involvement.
- Complementary and alternative medicine therapies should be chosen according to the patient's functional status, belief or religious perspectives, access to health care, and insurance coverage.
- Some complementary and alternative medicine therapies may alter physiological responses, thereby requiring changes in routine medication doses.
- Imagery is usually visual but can also involve the auditory, gustatory, and olfactory senses.
- Many complementary and alternative medicine therapies lack a scientific basis but are thought to be effective on the basis of observed positive outcomes in a number of patients. Some complementary and alternative medicine therapies are

supported by research published in professional nursing and medical journals.

- Current research supports various nutritional practices that limit the development of lifestyle-specific diseases.
- Not all natural health products are safe.

❖ CRITICAL THINKING EXERCISES

Patient profile: Margaret is a 76-year-old Catholic woman who has received a diagnosis of a slow-growing renal tumour. Surgery is scheduled in two weeks, and Margaret is afraid of both the procedure and the outcome. Is it cancer? Will the surgery result in a disability?

1. What specific nursing-accessible complementary and alternative medicine interventions can you offer Margaret to prepare her for the surgery and reduce her anxiety?
2. After surgery, Margaret becomes depressed. What complementary and alternative medicine therapies may be appropriate to help her deal with her depression?

❖ REVIEW QUESTIONS

1. Despite the success of allopathic medicine (traditional Western medicine), many patients find complementary therapies provide relief for which of the following conditions?
 1. Heart disease and pancreatitis
 2. Ulcers and hepatitis
 3. Chronic back pain and arthritis
 4. Lupus and diabetes
2. Many complementary therapies, such as acupuncture, have diagnostic and therapeutic methods specific to their field. Which therapies can be easily learned and used as part of independent nursing practice?
 1. Massage therapy
 2. Chinese medicine
 3. Shamanism
 4. Imagery

3. Which of the following statements best describes the experience of Canadians who have used a complementary and alternative medicine therapy?
 1. Most used complementary and alternative medicine therapy to prevent illness or maintain wellness.
 2. Few found these therapies helpful.
 3. Most had their complementary and alternative medicine therapy is covered by medicare.
 4. Most are from lower socioeconomic backgrounds.
4. Which of the following does holistic nursing regard and treat?
 1. Mind, body, and spirit
 2. Disease, spirit, and family
 3. Desires and emotions
 4. Muscles, nerves, and spine disorders
5. After you complete your assessment of the patient, whose permission is required before you can implement a complementary and alternative medicine therapy?
 1. The patient's
 2. The physician's
 3. The family's
 4. No permission is required.
6. According to one of the principles of complementary and alternative medicine therapies, which of the following statements best describes the individual who receives treatment?
 1. Actively involved in the treatment
 2. A total believer in what is being taught
 3. Submissive to the practitioner
 4. Less competent in his or her own care
7. Which of the following describes the most effective use of St. John's wort?
 1. Antioxidant
 2. Anti-inflammatory
 3. Mild antidepressant
 4. Vasodilator
8. Meditation may augment the effects of which of the following medications?
 1. Antihypertensive medications
 2. Insulin and vitamins
 3. Prednisone
 4. Cough syrups and aspirin
9. Biofeedback techniques are frequently used in addition to relaxation interventions to assist individuals to do which of the following?
 1. Eat less food
 2. Learn to control specific autonomic nervous system responses
 3. Control diabetes
 4. Live longer with human immunodeficiency virus (HIV)
10. Therapeutic touch is a training-specific therapy that was developed by which profession?
 1. Medicine
 2. Nursing
 3. Physiotherapy
 4. Occupational Therapy

✦ RECOMMENDED WEB SITES

Canadian College of Naturopathic Medicine: <http://www.ccnm.edu>

The Web site provides detailed information about the four-year, full-time program offered by this professional college of naturopathic medicine. The site includes a resource centre with links to other Web sites.

Canadian Interdisciplinary Network for Complementary and Alternative Research (IN-CAM): <http://www.incamresearch.ca/index.php?home&lng=en>

This network facilitates research, knowledge, and education about CAM in Canada. Links to other associated networks and institutions are provided.

Chinese Medicine and Acupuncture Association of Canada: <http://www.cmaac.ca/>

This organization aims to raise the profile and reputation of Chinese medicine and acupuncture. The site includes the organization's history and a Canada-wide members' index.

College of Nurses of Ontario: Practice Guideline: Complementary Therapies: http://www.cno.org/Global/docs/prac/41021_CompTherapies.pdf

Information on complementary therapies and their application to nursing practice in Ontario can be found at this site, including guidelines for practice.

ConsumerLab: <http://www.consumerlab.com/>

The quality and quantity of ingredients in various brands of NHPs are independently tested by this organization. General use is free, but a small yearly fee is required to access the entire database.

M. D. Anderson Cancer Center: <http://www.mdanderson.org/education-and-research/departments-programs-and-labs/programs-centers-institutes/integrative-medicine-program/index.html>

The information provided here about complementary medicine and how it can be integrated with allopathic medicine is useful to both health care providers and the public.

National Center for Complementary and Alternative Medicine: <http://nccam.nih.gov/>

The center provides information on various NHPs, research, and ongoing clinical trials related to CAM. It also gives links to a variety of other resources and institutions related to complementary and alternative medicines.

Natural Health Products Directorate: <http://www.hc-sc.gc.ca/dhp-mps/prodnatur/index-eng.php>

This directorate is Health Canada's regulating authority for NHPs for sale in Canada. The site includes information on the regulatory practices, definitions related to NHPs, and an index of various health-related issues.

Public Health Agency of Canada: <http://www.phac-aspc.gc.ca/index-eng.php>

The agency's focus is on efforts to prevent chronic diseases, injuries, and public health emergencies. The agency works closely with provinces and territories to keep Canadians healthy and reduce pressures on the health care system.

Activity and Exercise

Written by Donna J. Gill, RN(EC), BScN, MSc, CRN(C)

Based on the original chapter by Rita Wunderlich, RN, PhD

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Describe the role of the musculoskeletal and nervous systems in the regulation of movement.
- Discuss physiological and pathological influences on body alignment and joint mobility.
- Describe how to use proper body mechanics and ergonomics to prevent musculoskeletal injuries.
- Describe how exercise and activity benefit physiological and psychological functioning.
- Describe the benefits of implementing an exercise program for the purpose of health promotion.
- Describe the benefits of implementing exercise and activity during the acute, restorative, and continuing care of patients.
- Describe important factors to consider when planning an exercise program for patients across the lifespan and for those with specific chronic illnesses.
- Assess patients for impaired mobility and activity intolerance.
- Formulate nursing diagnoses for patients who experience impaired mobility and activity intolerance.
- Write a nursing care plan for a patient with impaired mobility and activity intolerance.
- Describe the interventions for maintaining activity tolerance and mobility during the acute, restorative, and continuing care of patients.
- Evaluate the nursing care plan for maintaining activity and exercise for patients across the lifespan and with specific chronic illnesses.

When providing nursing care, you will walk, turn, lift, and transfer. You use muscles and leverage when carrying out these activities. To reduce the risk of injury to the patient or yourself, you must understand and practise proper **body mechanics**, as well as use safe lifting and moving techniques. To prevent injury to yourself when performing other nursing tasks, such as pushing medication carts or stretchers, using the telephone, and documenting patient care, attention to **ergonomics** is equally important. Understanding both body mechanics and ergonomics includes knowledge of the actions of various muscle groups, knowledge of the

The chapter author would like to thank Lisa Baumung, OT Reg (Ont), Occupational Therapist; Lynn Bennett, BSc, P.T., Physiotherapist; and Anne Rocchi, BSc, MEng, Director, Occupational Health, Safety & Wellness, for their assistance with this chapter.

► BOX 35-1 The Gift of Exercise

The other day I was looking for a gift to give to a friend. This friend is very important to me and I want her to be around for a long time. I want her to live a long and healthy life. I thought how great it would be if I could give her a gift that would improve the quality of her life.

So I sat down and made a list of what I would look for in this special gift:

It would help her to be stronger, firmer, leaner, more flexible, and energetic.

It would help lower her risk of dying from heart disease, help lower blood pressure and improve lipid profile, control her blood glucose level, fight obesity, and help her to age more gracefully.

It would help improve immune function, concentration and task performance, and the quality of sleep.

It would help reduce stress, improve mood, enhance self-esteem, and increase optimism and confidence.

It would help to increase self-awareness and control over the choices in her life.

It would be fun but also challenging.

It would allow for socialization but also time alone, depending on her needs.

It would come in all different modes and styles and adapt to various environments and weather conditions.

Finally, it would have a solid *Consumer Reports* rating, supported by scientific data from reputable sources.

After completing my list, I realized that the only gift that meets all the above criteria is the gift of exercise. Have a happy and healthy life, my friend.

Source: Huddleston, J. S. (2006). Exercise. In C. L. Edelman & C. L. Mandle (Eds.), *Health promotion throughout the lifespan* (6th ed.). St Louis, MO: Mosby.

factors involved in the coordination of body movement, and familiarity with the integrated functioning of the skeletal, muscular, and nervous systems. This chapter focuses on body mechanics and you, the nurse, whereas Chapter 45 discusses body mechanics in relation to the patient.

Nurses must promote activity and **exercise** because of the beneficial impact on wellness, prevention of illness, and restoration of optimal functioning. A program of regular physical activity and exercise has the potential to enhance all dimensions of wellness (Box 35-1). This chapter provides information about exercise and activity as it relates to health promotion of patients. The discussion of activity and exercise is equally important to you, the nurse. Nursing strategies are included to help plan an individualized exercise and activity program for a variety of patients, including those with specific chronic diseases. Nursing strategies for a patient who is acutely ill or has significant mobility issues are discussed in Chapter 45.

Scientific Knowledge Base

Activity and exercise are important to the well-being of all individuals. You will be able to provide safe and effective assistance to patients by knowing the physiology of body movement and principles of body mechanics.

Physiology of Movement

Coordinated body movement involves the integrated functioning of the skeletal, muscular, and nervous systems. Because these three systems cooperate so closely in the mechanical

support of the body, they are often considered as a single functional unit.

Skeletal System. The skeletal system or bones perform five functions in the body: support, protection, movement, mineral storage, and hematopoiesis (blood cell formation). In a discussion of body mechanics, two of these functions—support and movement—are most important (Thibodeau & Patton, 2007).

The skeleton provides attachment sites for muscles and ligaments, and the leverage necessary for movement. It is the body's supporting framework and consists of four types of bones: long, short, flat, and irregular. **Long bones** contribute to height (e.g., the femur, fibula, and tibia in the leg) and length (e.g., the phalanges of the fingers and toes). **Short bones** occur in clusters and, when combined with ligaments and cartilage, permit movement of the extremities. Two examples of short bones are the tarsal bones in the foot and the patella in the knee. **Flat bones** provide structural contour, such as bones in the skull and the ribs in the thorax. **Irregular bones** make up the vertebral column and some bones of the skull, such as the mandible.

Bones are further characterized by firmness, rigidity, and elasticity. Firmness results from inorganic salts, such as calcium and phosphate, that are laid down in the bone matrix. Firmness is related to the bone's rigidity, which is necessary to keep long bones straight and enables bones to bear weight. In addition, bones have a degree of elasticity and flexibility that changes with age. For example, newborns have a large amount of cartilage and are highly flexible, but their bones are unable to support weight. Toddlers' bones are more pliable than those of older people and thus are better able to withstand falls. Older adults, especially women, are more susceptible to bone loss (resorption) and osteoporosis. Osteoporosis Canada (2011) estimates that one in four women over age 50 and one in eight men over age 50 has osteoporosis.

The skeletal system has several other functions. Bones protect vital organs (e.g., the skull around the brain; the ribs around the heart and lungs). They also aid in calcium regulation, store calcium, and release calcium into the body's circulation as needed. Patients with decreased calcium regulation and metabolism are at risk for developing osteoporosis and **pathological fractures** (fractures caused by weakened bone tissue) (Walker, 2008). Eighty percent of fractures in Canadians over 60 are related to osteoporosis (Osteoporosis Canada, 2011). In addition, the internal structure of bones contains bone marrow, which participates in red blood cell (RBC) production (hematopoiesis) and acts as a reservoir for blood. Patients with altered bone marrow function or diminished RBC production are usually weakened and fatigue easily, which decreases their mobility and places them at risk of falling.

Joints, ligaments, tendons, and cartilage permit strength and flexibility of the skeleton. Strength enables the skeletal system to support the body.

Joints. Joints or articulations are the connections between bones. Each joint is classified according to its structure and degree of mobility. Joints are classified as four types: synarthrotic, cartilaginous, fibrous, and synovial (Huether & McCance, 2008). A person's flexibility is demonstrated through **range of motion (ROM)**, which is the range of normal movement for a joint.

In a **synarthrotic joint**, bones are jointed by bones. No movement is associated with this type of joint, and the bony tissue that forms between the bones provides strength and

Figure 35-1 Joint types. A, Synarthrotic. B, Cartilaginous. C, Fibrous. D, Synovial.

stability. The classic example of this type of joint is the sacrum, in which vertebrae are joined (Figure 35-1, A).

The **cartilaginous joint**, or **synchondrodial joint**, has little movement but is elastic and uses cartilage to unite body surfaces. Cartilaginous joints are found when bones are exposed to constant pressure, such as the costosternal joints between the sternum and ribs (Figure 35-1, B).

The **fibrous joint**, or **syndesmodial joint**, is a joint in which two bony surfaces are united by a ligament or membrane. The fibres of ligaments are flexible and stretch, permitting a limited amount of movement. For example, the paired bones of the lower leg (tibia and fibula) are fibrous joints (Heuther & McCance, 2008) (Figure 35-1, C).

The **synovial joint**, or true joint, is a freely movable joint in which contiguous bony surfaces are covered by articular cartilage and connected by ligaments lined with a synovial membrane. Joining of the humeral radius and ulna by cartilage and ligaments forms a pivotal joint (Figure 35-1, D). Other types of synovial joints are the ball-and-socket joints (e.g., hip joint) and the hinge joints (e.g., interphalangeal joints of the fingers).

Ligaments. Ligaments are white, shiny, flexible bands of fibrous tissue that bind joints together and connect bones and cartilages. Ligaments are elastic and aid joint flexibility and support (Figure 35-2). In addition, some ligaments have a protective function. For example, ligaments between the vertebral bodies and the ligamentum flavum prevent damage to the spinal cord during movement of the back.

Tendons. Tendons are white, glistening, fibrous bands of tissue that connect muscle to bone. Tendons are strong, flexible, and inelastic, and they occur in various lengths and thicknesses. The Achilles tendon (tendo calcaneus) is the thickest and strongest tendon in the body. It begins near the middle of the posterior of the leg and attaches the gastrocnemius and soleus muscles in the calf to the calcaneal bone in the back of the foot (Figure 35-3).

Figure 35-2 Ligaments of the hip joint.

Cartilage. Cartilage is nonvascular, supporting connective tissue with flexibility similar to that of firm plastic. The gristle-like nature of cartilage permits it to sustain weight and to serve as a shock absorber between articulating bones. It is located chiefly in the joints and thorax, trachea, larynx, nose, and ear. The fetus has a large amount of temporary cartilage, which is replaced by bone developed during infancy. Permanent cartilage is unossified (not hardened), except in advanced age and in diseases such as osteoarthritis.

Skeletal Muscle. Skeletal muscles allow for movement and determine the form and contour of the body. There are more than 600 skeletal muscles in the body. Movement of bones and joints involves active processes that must be

Figure 35-3 Tendons and muscles of the lower leg.

carefully integrated to achieve coordination. Skeletal muscles, because of their ability to contract and relax, are the working elements of movement. Contractile elements of the skeletal muscle are enhanced by anatomical structure and attachment to the skeleton. Adequate skeletal muscle is necessary for strength and flexibility (Thibodeau & Patton, 2007).

Muscles are made of fibres that contract when stimulated by an electrochemical impulse that travels from the nerve to the muscle across the neuromuscular junction. The electrochemical impulse causes the filaments (predominantly protein molecules of myosin and actin) within the fibre to slide past each other, with the filaments changing length.

Muscle contractions can be categorized by functional purpose: moving, resisting, or stabilizing body parts. In **concentric tension**, increased muscle contraction causes muscle shortening, resulting in movement, such as when a patient uses an overhead trapeze to pull up in bed. **Eccentric tension** helps to control the speed and direction of movement as the muscle lengthens. In the example of the overhead trapeze, the patient should slowly lower to the bed. This lowering is controlled when the muscles lengthen. Concentric and eccentric muscle actions are necessary for active movement and are therefore referred to as dynamic or **isotonic contraction**. In contrast, static or **isometric contraction** causes an increase in muscle tension or muscle work but no shortening or active movement of the muscle (e.g., instructing the patient in tightening and relaxing a muscle group, as in quadriceps set exercises or pelvic floor muscle exercises). Voluntary movement is a combination of isotonic and isometric contractions. For example, when you lift a patient up in bed, the patient's weight causes increased tension in the muscles of your arms until the tension (isometric) is equal to the weight to be lifted and the weight of your lower arms. When this equilibrium is reached, continued stimulation of the muscles results in muscle shortening (isotonic) and bending of the elbows (active movement), and the patient is lifted off the bed.

Although isometric contractions do not result in muscle shortening, energy expenditure is increased. This type of muscle work is comparable to having a car in neutral while the driver continually depresses the accelerator and races the engine. The car is not going anywhere but the driver still expends a large amount of energy. You, as the nurse, must recognize the energy expenditure (increased respiratory rate and increased work on the heart) associated with isometric exercises because these types of exercises may be contraindicated in certain illnesses or conditions (e.g., myocardial infarction or chronic obstructive pulmonary disease).

Muscles Concerned With Movement. The muscles of movement are located near the skeletal region, where movement is caused by a lever system (Thibodeau & Patton, 2007). The lever system makes the work of moving a weight or load easier. In the human body, it occurs when specific bones act as a lever. The human forearm is an application of the lever: the elbow acting as the fulcrum, the weight held in the hand and being lifted acting as the resistance, and the pull of the muscles between the elbow and the hand acting as the effort. Muscles that attach to bones involved in lever systems provide the necessary strength to move the object.

Muscles Concerned With Posture. Gravity pulls on parts of the body all the time; the only way that the body can be held in position is for muscles to exert pull on bones in the opposite direction. Muscles accomplish this counterforce by maintaining a low level of sustained contraction. Because poor posture represents a stance that is less than optimal for counteracting the force of gravity, it places more work on muscles. This leads to fatigue and can eventually interfere with bodily functions and cause deformities.

Muscle Groups. The antagonistic, synergistic, and anti-gravity muscle groups are coordinated by the nervous system and maintain posture and initiate movement. **Antagonistic muscles** bring about movement at the joint. During movement, the active mover muscle contracts, and its antagonist relaxes. For example, during flexion of the arm, the active mover (the biceps brachii) contracts and its antagonist (the triceps brachii) relaxes. During extension of the arm, the active mover, now the triceps brachii, contracts and the new antagonist, the biceps brachii, relaxes.

Synergistic muscles contract to accomplish the same movement. When the arm is flexed, the strength of the contraction of the biceps brachii is increased by contraction of the synergistic muscle, the brachialis. Thus, with synergistic muscle activity, two active movers—the biceps brachii and the brachialis—contract, and the antagonistic muscle, the triceps brachii, relaxes.

Antigravity muscles are involved with joint stabilization. These muscles continuously oppose the effect of gravity on the body and permit a person to maintain an upright or sitting posture. In an adult, the antigravity muscles are the extensors of the leg—the gluteus maximus, the quadriceps femoris, and the soleus muscles—and the muscles of the back.

Skeletal muscles support posture and carry out voluntary movement. These muscles are attached to the skeleton by tendons, which provide strength and permit motion. The movement of the extremities is voluntary and requires coordination from the nervous system.

Nervous System. Movement and posture are regulated by the nervous system. The major voluntary motor area, located in the cerebral cortex, is the precentral gyrus, or motor strip. A majority of motor fibres descend from the motor strip and cross

at the level of the medulla. Thus, the motor fibres from the right motor strip initiate voluntary movement for the left side of the body, and the motor fibres from the left motor strip initiate voluntary movement for the right side of the body.

Transmission of the impulse from the nervous system to the musculoskeletal system is an electrochemical event and requires a neurotransmitter. Neurotransmitters are chemicals (e.g., acetylcholine) that transfer the electrical impulse from the nerve across the myoneural junction to stimulate the muscle, causing movement.

Movement can be impaired by disorders that alter neurotransmitter production, as in Parkinson's disease; alter transfer from the neurotransmitter to the muscle, as in myasthenia gravis; or alter activation of muscle activity, as in multiple sclerosis (Huether & McCance, 2008).

Proprioception. Proprioception is the awareness of the position of the body and its parts (Huether & McCance, 2008). Position is monitored by proprioceptors located on nerve endings in muscles, tendons, and joints. **Posture** is regulated by the nervous system and requires coordination of proprioception and balance. As a person carries out **activities of daily living (ADLs)**, proprioceptors monitor muscle activity and body position. For example, the proprioceptors on the soles of the feet contribute to correct posture during standing or walking. During standing, pressure is continuous on the bottom of the feet. The proprioceptors monitor the pressure, communicating this information through the nervous system to the antigravity muscles. The standing person remains upright until deciding to change position. As a person walks, the proprioceptors on the bottom of the feet monitor pressure changes. Thus, when the bottom of the moving foot comes in contact with the walking surface, the individual automatically moves the stationary foot forward. The proprioceptors allow people to walk without having to watch their feet.

Balance. A person must have adequate balance when standing, running, lifting, or performing ADLs. Balance is controlled by the nervous system, specifically by the cerebellum and the inner ear. A major function of the cerebellum is to coordinate all voluntary movement, particularly highly skilled movements, such as those required in skiing.

Within the inner ear are the semicircular canals, three fluid-filled structures that assist in maintaining balance. Fluid within the canals has a certain inertia, and when the head is suddenly rotated in one direction, the fluid remains stationary for a moment, whereas the canal turns with the head. This allows a person to change position suddenly without losing balance.

Principles of Body Mechanics

Good body mechanics is the use of correct muscles to complete activities safely and efficiently, without unnecessary strain on any muscle or joint. It involves the coordinated efforts of the musculoskeletal and nervous systems to maintain body alignment, balance, and posture during activity and exercise. This applies to the patient and the nurse. Nursing activities may include lifting, bending, moving, and performing ADLs. Using the principles of proper body mechanics during routine activities reduces the risk of injury to the nurse and the patient (Box 35-2).

Keep in mind that nurses spend a good deal of time performing other tasks, ones not directly associated with their patients. Other activities often include standing or sitting at desks and computers to document care, collaborating with other members of the health team, and preparing equipment

BOX 35-2 Principles of Body Mechanics

- The wider the base of support, the greater the stability.
- The lower the centre of gravity, the greater the stability.
- The equilibrium of an object is maintained as long as the line of gravity passes through its base of support.
- Facing the direction of movement prevents abnormal twisting of the spine.
- Dividing balanced activity between arms and legs reduces the risk of back injury.
- Leverage, rolling, turning, or pivoting requires less work than lifting.
- When friction is reduced between the object to be moved and the surface over which it is moved, less force is required to move it.
- Reducing the force of work reduces the risk of injury.
- Maintaining good body mechanics reduces fatigue of the muscle groups.
- Alternating periods of rest and activity helps to reduce fatigue.

and supplies. All these activities require as much attention to proper body mechanics as does hands-on patient care.

Body Alignment. Body alignment refers to the relationship of one body part to another body part along a horizontal or vertical line. Correct alignment reduces the strain on musculoskeletal structures, maintains adequate **muscle tone**, and contributes to balance.

Body Balance. Body balance is achieved when a relatively low **centre of gravity** is balanced over a wide, stable base of support and a line falls from the centre of gravity vertically through the base of support. The base of support is the foundation. When the line from the centre of gravity does not fall vertically through the base of support (that is, when the line is on an angle other than 90 degrees), the body loses balance. Body balance is also enhanced by proper posture, or the body position that most favours function, requires the least muscular work to maintain, and places the least strain on muscles, ligaments, and bones (Thibodeau & Patton, 2007).

Use balance to maintain proper body alignment and posture by taking two simple actions. First, widen the base of support by separating your feet to a comfortable distance. Second, bring the centre of gravity closer to the base of support; do this by bending your knees and flexing your hips until you are squatting yet maintaining proper back alignment by keeping your trunk erect.

Friction. Friction is a physical force—the resistance encountered during the act of rubbing one object against another (Myers, 2009). Because it opposes movement, you are more likely to experience a musculoskeletal injury as a result of friction (and the patient may suffer a friction abrasion) if you are not careful. To minimize the chance of such injuries, reduce friction by following some basic principles:

- Avoid lifting or moving patients manually. Using a mechanical lift completely prevents friction.
- In situations when you must assist a patient to move manually, use a friction-reducing device such as a slider sheet, slide board, or transfer board to reduce friction.
- When possible, use some of the patient's strength and mobility to assist with transferring or moving the patient in bed. For instance, if patients can bend their knees as you assist them in moving up in bed, friction is decreased. Explain the procedure and tell the patient when to move (see Chapter 45).

- The greater the surface area of the object to be moved, the greater the friction. If a patient is unable to assist in moving up in bed, placing the patient's arms across the chest decreases surface area and reduces friction.

Pathological Influences on Body Mechanics and Movement

Many pathological conditions affect body alignment and movement and hence the capacity for exercise and activity. These conditions include congenital abnormalities, degenerative diseases, and episodic illnesses affecting bones, joints, muscles, and the central nervous system. Chronic diseases affecting the internal organs can also affect an individual's capacity for activity and exercise.

Congenital Abnormalities. Congenital abnormalities affect musculoskeletal alignment, balance, and appearance. For example, osteogenesis imperfecta is an inherited disorder characterized by bones that are porous, short, bowed, and deformed; as a result, children with this disorder experience curvature of the spine and shortness of stature (Hockenberry-Eaton & Wilson, 2008). Scoliosis is a structural curvature of the spine associated with vertebral rotation. Muscles, ligaments, and other soft tissues become shortened as a result. Balance and mobility are affected in proportion to the severity of abnormal spinal curvatures (Hockenberry-Eaton & Wilson, 2008).

Degenerative Diseases. Degenerative diseases are those that affect an individual's health and abilities over time, generally in a progressively deteriorating way. Degenerative diseases of the nervous system such as Parkinson's disease or multiple sclerosis can affect an individual's control of movement and balance. Diseases of the skeletal system such as osteoporosis and osteomalacia weaken the bones and make them more prone to fractures. An autoimmune system disorder such as rheumatoid arthritis is characterized by inflammation and destruction of the synovial membrane and articular cartilage resulting in pain in the joints (Huether & McCance, 2008).

Other Chronic Diseases. Many chronic diseases of the internal organs also affect an individual's ability to be active and exercise. Diseases of the heart such as coronary artery disease and heart failure can alter tissue perfusion and hence activity tolerance. Chronic diseases of the lungs such as asthma and chronic obstructive pulmonary disease can impair gas exchange, thus also affecting activity tolerance. Diabetes, chronic renal impairment, and various cancers can all similarly affect one's ability to exercise.

Episodic Illnesses. Episodic illnesses affecting movement and exercise include anything that brings about an abrupt change in the bones, joints, muscles, or central nervous system. These can include musculoskeletal trauma such as sprains or fractures and neuromuscular conditions such as spinal cord injuries, brain injuries, or cerebrovascular accidents (CVA or stroke). These often result in a period of reduced mobility followed by a period of rehabilitation and thus are described in more detail in Chapter 45.

Exercise and Activity

Exercise is physical activity for the purpose of conditioning the body, improving health, and maintaining fitness, or it may be used as a therapeutic measure. When a person exercises, physiological changes occur in body systems (Box 35-3). The exercise program chosen and developed for a patient depends on that individual's **activity tolerance**, or the kind and amount of

BOX 35-3 Effects of Exercise

Cardiovascular System

Increased cardiac output
Improved myocardial contraction, thereby strengthening cardiac muscle
Decreased resting heart rate
Improved venous return

Pulmonary System

Increased respiratory rate and depth followed by a quicker return to resting state
Improved alveolar ventilation
Decreased work of breathing
Improved diaphragmatic excursion

Metabolic System

Increased basal metabolic rate
Increased use of glucose and fatty acids
Increased triglyceride breakdown
Increased gastric motility
Increased production of body heat

Musculoskeletal System

Improved muscle tone
Increased joint mobility
Improved muscle tolerance to physical exercise
Possible increase in muscle mass
Reduced bone loss

Activity Tolerance

Improved tolerance
Decreased fatigue

Psychosocial Factors

Improved tolerance to stress
Reports of "feeling better"
Reports of decrease in illness (e.g., colds, influenza)

Sources: Based on Huether, S. E., & McCance, K. L. (2008). *Understanding pathophysiology* (2nd ed.). St. Louis, MO: Mosby; and Hoeman, S. P. (2008). *Rehabilitation nursing: Process, application, and outcomes* (4th ed.). St Louis, MO: Mosby.

exercise or activity that the individual is able to perform. Physiological, emotional, and developmental factors influence the patient's activity tolerance.

A program of regular physical activity and exercise promotes physical and psychological health. An active lifestyle is important for promoting and maintaining health and is also an essential treatment modality for chronic illnesses. Regular physical activity and exercise enhance functioning of all body systems, including cardiopulmonary functioning (endurance), musculoskeletal fitness (strength, flexibility, and bone integrity), weight control and maintenance, and psychological well-being (body image) (Huddleston, 2006; Warburton et al., 2010).

The best program of physical activity includes a combination of exercises that produce different physiological and psychological benefits. Isotonic, isometric, and resistive isometric are three categories of exercise classified according to the type of muscle contraction involved. Isotonic exercises cause muscle contraction and changes in muscle length (isotonic contraction). Walking, swimming, dance aerobics, jogging, bicycling, and moving arms and legs with light resistance are examples

of isotonic exercises. The benefits of isotonic exercises include increased circulatory and respiratory functioning, increased osteoblastic activity (activity by bone-forming cells) to combat osteoporosis, and increased muscle tone, mass, and strength.

Isometric exercises involve tightening a muscle and holding it for a number of seconds in a stationary position while maintaining the tension (isometric contraction). This form of exercise is ideal for patients who are unable to tolerate the increase in activity expected during isotonic exercises. Isometric exercises are especially helpful to people who are recovering from injuries that limit range of motion. For example, *quad setting*—pressing the knee toward the bed and holding—is used after knee surgery. Benefits of isometric exercises include minimized potential for muscle wasting by increasing muscle mass, tone, and strength; increased circulation to the involved body part; and increased osteoblastic activity.

Isometric exercises also may be resistive. Resistive isometric exercises are those in which the individual contracts the muscle while pushing against a stationary object or resisting the movement of an object (Hoeman, 2008). A gradual increase in the amount of resistance and in the length of time that the muscle contraction is held will increase muscle strength and endurance. The *plank* (for abdominal strengthening) and the *wall push-up* (for chest, tricep, and shoulder strengthening) are resistive isometric exercises with which you may be familiar. The patient who is in a sitting position may do *hip lifting*, in which the hands push against a surface such as the seat of a chair to raise the hips. After hip surgery, *gluteal setting* is prescribed: in a supine position, keeping the legs straight, together, and in contact with the bed, with a loop or belt positioned around the thighs just above the knees, press legs outward against the belt and hold. Resistive isometric exercises help to promote muscle strength and provide sufficient stress against bone to promote osteoblastic activity.

Nursing Knowledge Base

This section is concerned with knowledge from areas of nursing practice that enable you to meet the holistic needs of the patient. Developmental changes, behavioural aspects, environmental issues, cultural and ethnic influences, and family and social support are important aspects of a person and must be incorporated into the plan of care, whether the patient is seeking health promotion, acute care, or restorative and continuing care.

Developmental Changes

Throughout the lifespan, the body's appearance and functioning undergo change. The greatest change and impact on the maturational process are observed at both ends of the developmental spectrum.

Infants Through School-Aged Children. The newborn infant's spine is flexed and lacks the anteroposterior curves of the adult. The first spinal curve occurs when the infant extends the neck from the prone position. As growth and stability increase, the thoracic spine straightens and the lumbar spinal curve appears, which allows sitting and standing.

The toddler's posture is awkward because of the slight swayback and protruding abdomen. As the child walks, the legs and feet are usually far apart and the feet are slightly everted. Toward the end of toddlerhood, posture appears less awkward, curves in the cervical and lumbar vertebrae are accentuated, and foot eversion disappears.

By the third year, the body is slimmer, taller, and better balanced. Abdominal protrusion is decreased, the feet are not as far apart, and the arms and legs have increased in length. The child appears more coordinated. The musculoskeletal system continues to grow and develop through adolescence (see Chapter 22).

Adolescence. The period of adolescence is usually initiated by a tremendous growth spurt. Growth is frequently uneven. As a result, the adolescent may appear awkward and uncoordinated. Adolescent girls usually grow and develop earlier than boys do. In girls, hips widen and fat is deposited in the upper arms, thighs, and buttocks. The adolescent boy's changes in shape are usually a result of long-bone growth and increased muscle mass (see Chapter 22).

Young to Middle-Aged Adults. An adult who has correct posture and body alignment feels good, looks good, and generally appears self-confident. The healthy adult also has the necessary musculoskeletal development and coordination to carry out ADLs. Normal changes in posture and body alignment in adulthood occur mainly in pregnant women. These changes result from the body's adaptive response to weight gain and the growing fetus (see Chapter 23). When pregnant, the woman's centre of gravity shifts toward the anterior. As a result, the pregnant woman leans back and is slightly swaybacked. She may complain of back pain.

Older Adults. A progressive loss of bone mass occurs in the older adult. Some of the possible causes of this loss are physical inactivity, hormonal changes, and increased osteoclastic activity (activity by cells responsible for bone tissue absorption). The effect of bone loss is weaker bones, causing vertebrae to be softer and long shaft bones to be less resistant to bending.

In addition, older adults may walk more slowly and appear less coordinated. They also may take smaller steps, keeping their feet closer together, which decreases their base of support. Thus, body balance may become unstable, and they are at greater risk for falls and injuries (see Chapter 24).

Changes in muscle tissue also occur as adults age, beginning as early as during the twenties for men and during the forties for women. Muscle fibres shrink and have reduced tone and contractility. Strength and endurance change; fatigue occurs more readily, and overall energy may be reduced (Paterson & Warburton, 2010).

safety alert Falls and the resulting injuries are among the most debilitating medical problems that prevent the older adult from remaining independent. Regular exercise that promotes strengthening, flexibility, and balance can help prevent falls in the older adult (Fahlman et al., 2007; Huddleston, 2006; Registered Nurses' Association of Ontario [RNAO], 2005).

Behavioural Aspects

Patients are more likely to incorporate an exercise program into their daily lives if it is supported and assisted by family and friends, nurses, physicians, and other members of the health care team. As the nurse, you should take into consideration the patient's knowledge of exercise and activity, barriers to a program of exercise and physical activity, and current exercise habits.

Patients are more open to developing an exercise program if they are at the stage of being ready to change their behaviour. Prochaska and DiClemente's Transtheoretical Model of

► BOX 35-4

General Strategies for Initiating and Maintaining an Exercise Program

An exercise program is most likely to be initiated and maintained when the individual

- Perceives a net benefit
- Chooses an enjoyable activity
- Feels competent doing the activity
- Feels safe doing the activity
- Can easily access the activity on a regular basis
- Can fit the activity into the daily schedule
- Feels that the activity does not generate financial or social costs that he or she is unwilling to bear
- Experiences a minimum of negative consequences such as injury, loss of time, negative peer pressure, and problems with self-identity
- Is able to successfully address issues of competing time demands
- Recognizes the need to balance the use of labour-saving devices and sedentary activities with activities that involve a higher level of physical exertion

Source: Adapted from Mayo Clinic: Healthy Lifestyle. (2011). *Fitness basics*. Retrieved from <http://www.mayoclinic.com/health/fitness/MY00396>.

Behaviour Change has been the most utilized model of understanding and facilitating behaviour change since it was developed in the 1980s. It identifies five stages individuals go through in implementing a lifestyle change: precontemplation, contemplation, preparation, action, and maintenance (Hutchinson et al., 2008). Information on the benefits of regular exercise may be helpful to the patient in the contemplation stage. Patients' decisions to change behaviour and include a daily exercise routine in their lives may occur gradually with the provision of repeated information that is individualized to their needs and lifestyle (Box 35-4). Once the patient has reached the action stage, you must develop, in collaboration with the patient, an exercise program that is customized to fit his or her needs. You then must provide continued follow-up support and assistance until the exercise program becomes a daily routine.

Environmental Issues

Work Sites. A common barrier for many patients is the lack of time needed to engage in a daily exercise program. Work sites have the potential to help their employees overcome the obstacle of time constraints by offering opportunities, reminders, and rewards for those committed to physical fitness (Health Canada, 2004; Box 35-5). Signs could be used to encourage employees to use the stairs instead of elevators. Rewards such as free parking or discounted parking fees could be given to employees who walk from distant lots (Canadian Fitness and Lifestyle Research Institute, 2006; Health Canada, 2004).

Schools. After many years of decreasing emphasis on physical education, it is increasingly clear that children are becoming less active, resulting in an increase in childhood obesity, high blood pressure, high cholesterol, and higher rates of depression (Flynn et al., 2006; Janssen & LeBlanc, 2010). Recently, daily physical activity or physical education has been mandated in elementary schools across Canada, but secondary schools are not keeping up (Active Healthy Kids Canada, 2007). Only 18% of Canadian teenagers accumulate

* BOX 35-5

FOCUS ON PRIMARY HEALTH CARE**A Work Site Diabetes Prevention Program**

Diabetes has so many potential complications, with associated economic and social costs, that all individuals, whether they are recognized as being at higher risk or not, should exercise as an essential primary prevention strategy.

In a recent study, prediabetic and previously undiagnosed diabetic employees participated in a 12-month diabetes prevention program at their work site. Registered nurses and a diabetic educator presented the three components of the program in both group and individual settings. Employees were encouraged to raise their level of physical activity, with membership in the employee fitness centre offered as an incentive. Dietary education focused especially on lowering fat intake. Behaviour change activities incorporated social support networks and consisted of identifying barriers to change in activity level and diet.

Aerobic fitness and a number of physiological measures improved significantly after 6 months and were maintained over the 12 months of the program. Significant improvement in glucose tolerance tests (GTT) and aerobic fitness continued for a full 24 months. More than half of the employees who participated in the study had normal GTT at two years.

The research by Aldana et al. (2006) demonstrates that implementation of education and exercise programs by occupational health nurses can have a strong influence on the well-being of employees. By reducing blood glucose below prediabetic and diabetic levels, workplace diabetes prevention programs can help prevent the onset of diabetes.

Source: Aldana, S., Barlow, M., Smith, R., Yanowitz, F., Adams, T., Loveday, L., & Merrill, R.M. (2006). A worksite diabetes prevention program: Two year impact on employee health. *American Association of Occupational Health Nurses Journal*, 54(9), 389-396.

enough daily activity to meet international guidelines for optimal growth and development (Canadian Fitness and Lifestyle Research Institute, 2006). Schools can provide a foundation for lifetime commitment to exercise and physical fitness by incorporating physical activity into a child's daily routine.

Community. The community's support of physical fitness can be instrumental in promoting the health of its members. Examples of community involvement to promote physical fitness are the provision of walking trails and track facilities in community parks and physical fitness classes offered by trained professionals. Cost constraints may make availability of such amenities challenging. However, success in implementing physical fitness programs depends on a collaborative effort between public health agencies, parks and recreational associations, provincial and local government agencies, health care agencies, and community members.

Cultural and Ethnic Influences

Exercise and physical fitness is beneficial to all human beings. When developing a physical fitness program for culturally diverse populations, you must consider what is motivating and what is deemed appropriate and enjoyable. For example, South Asians living in Canada have reported that their physical exercise has been limited because of weather, lack of motivation, embarrassment over clothing or appearance, and not

feeling comfortable participating in activities outside the home (South Asian Dietary Resource Working Group, 2007). Aerobic exercise in the form of dancing to songs from Bollywood movies is one culturally appropriate and community-based activity recommended for this population by the Working Group. Canadians from a traditional Chinese background value fitness activities based on Chinese culture—that is, activities that are gentle, soft, slow, relaxed, safe, and outdoor oriented (Lu et al., 2008). The Aboriginal population is another example of a group within Canada that has unique risk factors and traditions that must be taken into consideration when planning interventions for activity and exercise (Box 35-6).

Family and Social Support

Social support can be used as a motivational tool to encourage and promote exercise and physical fitness. The patient can engage a friend or a significant other to participate in a “buddy system” whereby they walk together each day at a specified time. This companionship provides for socialization and increases the enjoyment for some patients. It may lead to the development of a lifelong commitment to physical fitness.

* BOX 35-6 CULTURAL ASPECTS OF CARE

Epidemiological studies of ethnic groups indicate that physical inactivity is one of the risk factors associated with noninsulin-dependent diabetes mellitus (NIDDM). In Canada, NIDDM is between 3.6 and 5.3 times more prevalent within the Aboriginal population. Physical activity has been identified as playing an important role in the prevention and treatment of NIDDM, yet the Aboriginal population has a disproportionate number of poor, unemployed, and disadvantaged individuals who lack access to recreation and leisure activities.

Implications for Practice

- Because physical inactivity is a modifiable risk factor for the development of NIDDM, prevention and treatment programs need to focus heavily on exercise and to be tailored to the activity tolerance of the individual patient.
- Motivational factors incorporated into the exercise program, such as providing a healthy snack or meal for participants and furnishing each patient with a log to monitor weight loss and blood glucose levels, will enhance compliance.
- Promotion of physical activity should be supported by recognizing that a symbiotic relationship exists between cultural values and traditional leisure pursuits. Patients with a strong spiritual connection to the land may enjoy outdoor or wilderness recreation in the form of traditional games and activities, such as lacrosse and hunting.
- Ensure that members of Aboriginal groups collaborate in the planning and educational program initiatives.
- Development of an exercise or prevention program, or both, should attempt to remove potential barriers, such as transportation and cost, to facilitate commitment to the program.

Parents can support their children in sports and physical activity by providing encouragement, praise, and transportation and by participating themselves (Rhodes & Pfaeffli, 2010).

Critical Thinking

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking attitudes, and intellectual and professional standards. Patients' conditions are always changing. Clinical judgements require you to anticipate the information necessary, analyze the data, and make decisions regarding patient care.

To understand activity tolerance and physical fitness and their impact on the patient, you must integrate knowledge from nursing and other disciplines, previous experiences, and information gathered from patients. As you begin the process of problem solving for patient care, a variety of concepts must be considered together to provide the best outcome for the patient. The foundation for planning and decision making is knowledge of the musculoskeletal system and of health alterations that create problems for the patient in the area of activity, exercise, and body mechanics. In addition, you must stay current on and incorporate various guidelines, such as those supplied by the Canadian Diabetes Association (2008) and in the *Canadian Physical Activity Guidelines* developed by the Canadian Society of Exercise Physiology (2011). Your experiences and your ability to think creatively and critically enhance your approach to each new patient situation.

Many acquired, congenital, degenerative, and chronic conditions affect the structure of the musculoskeletal system and the function of the nervous system or impair activity tolerance to some degree. The impairment can be temporary or permanent. For patients with limited exercise capacity or activity tolerance, develop the nursing care plan to include interventions that maintain the present level of function with the goal of increasing the level of function.

Your experiences and your critical thinking attitude affect the problem-solving approach that is used with each new patient. Remember that patients have the capacity for improvement in spite of the impairments. Encouragement, support, commitment, creativity, and perseverance are important attitudes in critical thinking for these patients.

Nursing Process

❖ Assessment

Assessment of body alignment and posture is completed with the patient standing, sitting, or lying down. Use assessment to determine normal physiological changes in growth and development; deviations related to poor posture, trauma, muscle damage, or nerve dysfunction; and any learning needs of patients. In addition, during assessment you can observe their posture and obtain important information about other factors that contribute to poor alignment, such as inactivity, fatigue, malnutrition, and psychological problems. To gather relevant information, ask questions related to the patient's exercise and activity tolerance. During assessment (Figure 35-4), consider all the elements that contribute to making appropriate nursing diagnoses.

Put the patient at ease so that unnatural or rigid positions are not assumed. When assessing body alignment of a patient who is immobilized or unconscious, remove pillows and

Figure 35-4 Critical thinking model for activity and exercise assessment. CSEP, Canadian Society for Exercise Physiology.

positioning supports from the bed if not contraindicated, and place the patient in the supine position.

Body Alignment

Standing. An assessment of the patient who is standing should include looking for deviations in the following normal body alignment: the head should be erect and in the body's midline; body parts should be symmetrical; the spine should be straight with normal curvatures (cervical concave, thoracic convex, lumbar concave); the abdomen should be comfortably tucked; the knees should be in a straight line between the hips and ankles and should be slightly flexed; the feet should be flat on the floor and pointed directly forward and slightly apart to maintain a wide base of support; and the arms should hang comfortably at the sides (Figure 35-5). The patient's centre of gravity is in the midline, and the line of gravity is from the middle of the forehead to a midpoint between the feet. Laterally, the line of gravity runs vertically from the middle of the skull to the posterior third of the foot (Wilson & Giddens, 2005).

Sitting. An assessment of the patient in the sitting position should include looking for deviations in the following normal body alignment: the head should be erect and the neck and vertebral column in straight alignment; the body weight should be distributed on the buttocks and thighs; the thighs should be parallel and in a horizontal plane (be careful to avoid pressure on the popliteal nerve and blood supply); the feet

Figure 35-5 Correct body alignment when standing.

should be supported on the floor; and the forearms should be supported on the armrest, in the lap, or on a table in front of the chair.

Assessment of alignment in the sitting position is particularly important for the patient with muscle weakness, muscle paralysis, or nerve damage. A patient with these alterations has diminished sensation in affected areas and is unable to perceive pressure or decreased circulation. Proper sitting alignment reduces the risk of musculoskeletal system damage in such a patient.

Recumbent Position. An assessment of the patient in the recumbent position requires that the patient be placed in the supine position with all but one pillow and all positioning supports removed from the bed. The vertebrae should be in straight alignment without observable curves.

Conditions that create a risk of damage to the musculoskeletal system when lying down include impaired mobility (e.g., traction), decreased sensation (e.g., **hemiparesis** from a stroke), impaired circulation (e.g., diabetes), and lack of voluntary muscle control (e.g., spinal cord injuries).

When a patient is unable to change position voluntarily, assess the position of body parts while the patient is lying down. This is best done with you standing at the foot or head of the bed. The vertebrae should be in straight alignment without any observable curves. The extremities should be in alignment and not crossed over one another. The head and neck should be aligned without excessive flexion or extension.

Mobility

The assessment of mobility enables you to determine the patient's coordination and balance while the patient is walking, the ability to carry out ADLs, and the ability to participate in an exercise program. The assessment of **mobility** has four components: range of motion, gait, exercise, and activity tolerance.

Range of Motion. Assessing range of motion (ROM) is one assessment technique used to determine the degree of

damage or injury to a joint (see Chapter 31). These measurements enable you to answer questions about joint stiffness, swelling, pain, limitation of movement, and unequal movement. Limited ROM may indicate inflammation such as arthritis, fluid in the joint, altered nerve supply, or contractures. Increased mobility (beyond normal) of a joint may indicate connective tissue disorders, ligament tears, or possible joint fractures.

Gait. Gait, including rhythm, cadence, and speed, is the manner or style of walking. Walking with a limp is a gait. Propulsive, scissors, spastic, steppage, and waddling are descriptive names for other common gaits. Assessing gait allows you to draw conclusions about balance, posture, and the ability to walk without assistance. Note conformity; a regular, smooth rhythm; symmetry in the length of leg swing; smooth swaying related to the gait phase; and a smooth, symmetrical arm swing (Wilson & Giddens, 2005).

Exercise. Exercise is physical activity aimed at conditioning the body, improving health, maintaining fitness, or providing therapy to correct a deformity or restore the overall body to a maximal state of health. Determine how much exercise and the types of exercise that the patient participates in regularly. Ask the patient to describe the types of activities he or she does in a typical day or week. For greater accuracy, have the patient keep a diary of exercise activities for a week and review it together.

Activity Tolerance. Activity tolerance is the kind and amount of exercise or activity a person is able to perform. You need to assess activity tolerance when planning physical activity for health promotion and for patients with acute or chronic illness. This assessment provides the nurse with baseline data about the patient's activity patterns and assists in determining which factors (physical, psychological, or motivational) are affecting activity tolerance. Box 35-7 lists factors that affect activity tolerance.

Patient Expectations

In assessing the patient's expectations concerning activity and exercise, you will first need insight into the patient's perception of what is normal or acceptable with regard to physical fitness (Box 35-8). For example, one of the factors that affect physical activity is freedom from pain. If exercising is painful or fatiguing to the patient, compliance with and commitment to the desired interventions may be lacking. Patients may be content with their present physical activity and fitness and may not perceive a need for improvement. Unless a real threat to health maintenance exists, forcing the patient to accept your perspective is a breach of standards of care.

❖ Nursing Diagnosis

Assessment of the patient's activity tolerance, physical fitness, body alignment, and joint mobility provides related clusters of data or defining characteristics that help you identify a nursing diagnosis. You must be accurate when identifying diagnoses. For example, a patient who reports being tired or weakened potentially could be diagnosed as having activity intolerance or fatigue. Use defining characteristics to lead to the definitive diagnosis. For example, a finding of abnormal heart rate or dyspnea would lead you to the diagnosis of activity intolerance, not to fatigue.

When activity and exercise are problems for a patient, nursing diagnoses often focus on the individual's ability to

► BOX 35-7

Factors That Affect Physical Activity Tolerance

Physiological Factors

Skeletal abnormalities
Muscular impairments
Endocrine or metabolic illnesses (e.g., diabetes mellitus or thyroid disease)
Hypoxemia
Decreased cardiac function
Decreased endurance
Impaired physical stability
Pain
Sleep pattern disturbance
Prior exercise patterns
Infectious processes and fever

Emotional Factors

Anxiety
Depression
Chemical addictions
Motivation

Developmental Factors

Age
Gender

Pregnancy

Physical growth and development of muscle and skeletal support

Source: Adapted from Monohan, F. D., Sands, J. K., Neighbors, M., Marek, J. F., & Green-Nigro, C. J. (2007). *Phipps' medical-surgical nursing: Health and illness perspectives* (8th ed.). St Louis, MO: Mosby.

move. The diagnostic label should direct nursing interventions. This requires the correct selection of the related factors. For example, activity intolerance related to excess weight gain requires very different interventions than if the related factor is prolonged bed rest. Box 35-9 provides an example of how the diagnostic process leads to accurate diagnosis selection. The following are examples of nursing diagnoses related to activity and exercise:

- *Health-seeking behaviours*
- *Readiness for enhanced self-care*
- *Activity intolerance*
- *Ineffective coping*
- *Impaired gas exchange*
- *Risk for injury*
- *Impaired physical mobility*
- *Imbalanced nutrition: more than body requirements*
- *Acute or chronic pain*

❖ Planning

During planning, synthesize information from multiple resources (Figure 35-6). Your critical thinking ensures that the patient's care plan integrates all patient information. Best practice guidelines are especially important to consider when you develop a care plan as these documents establish scientifically based guidelines for selecting effective nursing interventions.

Concept maps assist in the planning of care. Figure 35-7 shows the relationship between a patient's medical diagnosis of heart failure and the identified nursing diagnosis.

► BOX 35-8 Nursing Assessment Questions

Nature of the Problem

- What types of problems are you having with physical activities and exercise?
- Why do you think your exercise and physical activity levels are inadequate?
- Describe your typical daily exercise routine and level of physical activity.
- What types of exercise do you prefer?
- How long do you exercise at any given time?

Signs and Symptoms

- Do you experience muscular or joint pain during or after exercise?
- Do you experience shortness of breath during physical activity?
- Do you experience chest discomfort or pain during exercise or physical activity?

Onset and Duration

- Which physical activities cause you to become short of breath?
- How long does it take to resume normal breathing after exercise or physical activity?

Severity

- How far do you walk before the pain in your legs begins?
- On a scale of 0 to 10 (with 10 being the worst discomfort), rate your leg pain.
- Describe your shortness of breath as minimal, moderate, or severe after physical activities or exercise, or both.

Barriers to Exercise and Activity

- Do you have any chronic illnesses that affect your ability to carry out activities of daily living (ADLs) or exercise?
- Do you have any physical limitations that prevent you from exercising on a daily basis?
- Do you have access to a community walking path or exercise equipment, or both?
- What prevents you from exercising 30 minutes each day?

Effect on Patient

- Has the lack of an exercise routine affected your weight?
- Have you felt more fatigued since you have not been able to exercise on a routine basis?
- Have you noticed any increase in shortness of breath when performing activities that require little exertion?

Goals and Outcomes. Once you identify the nursing diagnoses, you and the patient can set goals and expected outcomes to direct interventions. The plan should include consideration of preexisting health concerns and of any risks of injury to the patient. It is especially important to have knowledge of the patient's home environment when planning therapies to maintain or improve activity, body alignment, and mobility. For some patients with alterations in joint mobility, family members may be the providers of care. Include the patient's family in the care plan. The general goal related to exercise and activity is to improve or maintain the patient's motor function and independence. The following are examples of outcomes for patients with deficits in activity and exercise (Ackley & Ladwig, 2008):

- Participates in prescribed physical activity while maintaining appropriate heart rate, blood pressure, and breathing rate.

► BOX 35-9 NURSING DIAGNOSTIC PROCESS

Impaired Physical Mobility

Assessment Activities

Observe patient's gait.

Observe patient performing tasks such as feeding, dressing, or recreational activities.

Measure range of joint motion.

Defining Characteristics

Shuffled gait
Uncoordinated gait
Patient reports slower walking speed

Uncoordinated movements
Limited fine motor coordination

Reduced joint motion in lower and/or upper extremities
Stiffness in joints

Figure 35-6 Critical thinking model for activity and exercise planning.

- Shows an understanding of the need to increase activity gradually according to tolerance and symptoms
- Expresses understanding of the need to balance rest and activity

Setting Priorities. Care planning is individualized to the patient, taking into consideration the patient's most immediate needs. The immediacy of any problem is determined by the effect that the problem has on the patient's mental and

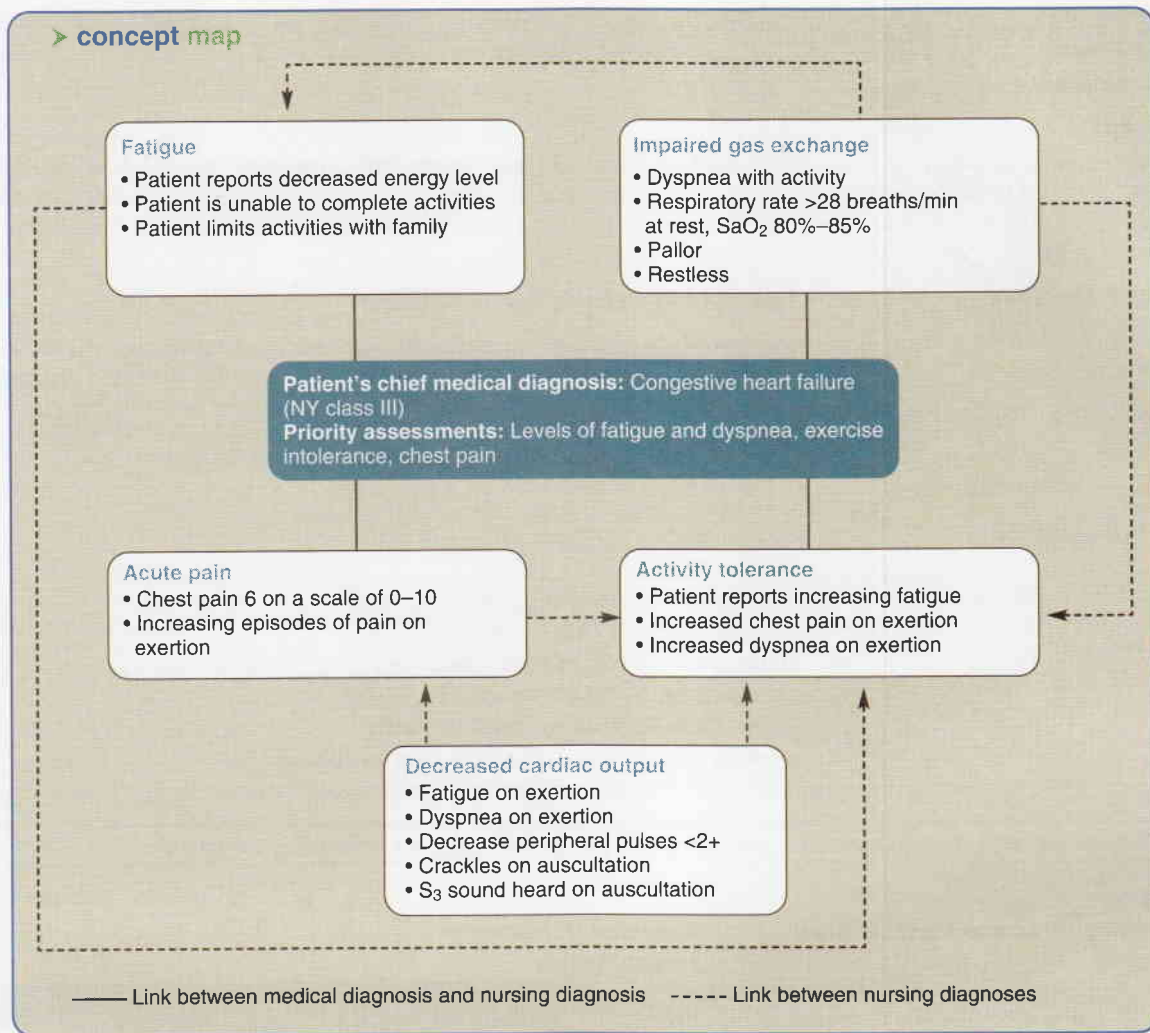

Figure 35-7 Concept map for a patient with heart failure and decreased activity.

physical health. For example, a patient may have chronic diseases such as diabetes and hypertension, which would be improved with an increase in exercise. However, if that same patient has recently experienced angina, immediate investigation and treatment of the angina is the priority.

Collaborative Care. Patients with complex medical problems or multiple co-morbidities may require the collaboration of multiple health care providers. Physicians, physiotherapists, kinesiologists, and occupational therapists may all be important for these patients. Formal rehabilitation programs may be necessary. In addition, always individualize a care plan to meet the actual and potential needs of the patient (see Box 35-10).

❖ Implementation

Health Promotion

A sedentary lifestyle contributes to the development of health-related problems. Promote health by encouraging patients to engage in a regular exercise program (Box 35-11). Discuss the recommendations for physical activity and fitness with the patient (Box 35-12). Design a program of exercise in collaboration with the patient, taking into account developmental (Box 35-13) and cultural factors (Box 35-14). For example, older

adults may be able to prevent functional decline and improve independence through routine completion of ADLs (Warburton et al., 2006).

Before starting an exercise program, patients should calculate their maximum heart rate by subtracting their current age in years from 220 and then determine their target heart rate by calculating 60% to 90% of this maximum rate. Patients should be taught to monitor their pulse during exercise and to exercise so that the heart rate is maintained within the target range.

Regardless of the exercise prescription implemented by the patient, warm-up and cool-down periods must be included in the program (Gillespie, 2006). The warm-up period usually lasts 5 to 10 minutes and may include stretching, calisthenics, and subsequent aerobic activity performed at a lower intensity. The warm-up period prepares the body and decreases the potential for injury. The cool-down period follows the exercise routine and usually lasts 5 to 10 minutes. The cool-down period allows the body to readjust to baseline functioning gradually and provides an opportunity to combine movement such as stretching with relaxation-enhancing mind-body awareness (Gillespie, 2006).

Many patients find it difficult to incorporate an exercise program into their daily routines because of time constraints.

► BOX 35-10 NURSING CARE PLAN

Activity Intolerance

Assessment

Mrs. Mary Wertenberger is a 45-year-old homemaker. She has enrolled in a cardiovascular disease prevention (CDP) program prescribed by her physician and conducted by Eric Sieple, a registered nurse. Mrs. Wertenberger has several risk factors associated with cardiovascular disease. She expresses feelings of stress resulting from excessive demands on her time. Eric's assessment included a discussion of Mrs. Wertenberger's current health problems as well as a pertinent physical examination.

Assessment Activities

Ask Mary what prompted her physician to recommend a CDP program.

Ask Mary about her exercise and eating habits.

Perform baseline assessment.

Findings and Defining Characteristics*

She responds, "I *gained 23 kg* over the past year. I become *fatigued* easily and lack the energy to keep up with even simple household chores. I don't want to leave the house anymore."

She responds, "I want to exercise but with the demands of child care and caring for my aging parents, I just don't feel like it. I feel pulled in every direction, that increases my stress, and then I want to eat, eat, eat!"

Height: 160 cm
Weight: 102 kg
Blood pressure: 152/90 mm Hg (at rest)
Pulse: 96 beats per minute (at rest)
Breathing rate: 20 breaths per minute (at rest)
Blood pressure: 164/96 mm Hg (climbing 10 steps)
Pulse: 120 beats per minute (climbing 10 steps)
Breathing rate: 36 breaths per minute (climbing 10 steps)

*Defining characteristics are shown in italics.

Nursing Diagnosis: Activity intolerance related to excessive weight gain, inactivity, and lack of cardiovascular fitness

Planning

Goals (Nursing Outcomes Classification)*

Patient will develop a plan of exercise that incorporates isotonic and isometric exercises.

Patient's activity tolerance will improve.

Patient's cardiopulmonary response to exercise will improve.

Expected Outcomes Health Beliefs

Patient will state the physiological and psychological effects of exercise. Patient will commit to performing physical exercise at home.

Activity Tolerance

Patient will perform and record exercise patterns three to four times over the next two weeks.

Patient's level of fatigue associated with exercise will remain the same or decrease.

Cardiovascular Pump Effectiveness

Patient's resting diastolic blood pressure will be below 80 mm Hg.

Patient's systolic blood pressure will be below 140 mm Hg. Patient's resting heart rate will range between 75 and 85 beats per minute.

*Outcome classification labels from Moorhead, S., Johnson, M., Maas, M. L., & Swanson, E. (Eds.). (2008). *Nursing outcomes classification (NOC)* (4th ed.). St Louis, MO: Mosby.

Interventions (Nursing Interventions Classification)*

Exercise Promotion

Instruct the patient about the physiological benefits of a regular exercise program.

Instruct the patient about the psychological benefits of a regular exercise program.

Develop a progressive plan of exercise with the patient, such as 3 to 5 km of brisk walking and quadriceps, biceps, and gluteal muscle isometric exercises three to four times per week.

Rationale

Physical activity and exercise protect against the development of cardiovascular disease (CVD) and decrease other risk factors associated with CVD, such as obesity, hypertension, and hyperlipidemia (Hamilton et al., 2007; Lloyd & Barnett, 2008; Sigal et al., 2006).

Physical activity and exercise increase self-esteem, feelings of enjoyment, self-confidence, and mood and decrease physical and psychological stress, anxiety, and depression (Paterson & Warburton, 2010).

Cross-training (a combination of exercise activities) provides variety to combat boredom and increases potential for total body conditioning (Huddleston, 2006).

► BOX 35-10 NURSING CARE PLAN—cont'd

Exercise Promotion

Instruct patient to use an exercise log and to record the day, time, duration, and responses (pulse, feelings, shortness of breath, daily weight).

Keeping a log may increase adherence to exercise prescription.

Schedule weekly meetings with the patient for follow-up and review of exercise log, progress, and barriers.

Patients are more likely to increase physical activity and remain compliant with an exercise program if they are counselled by a health care provider (Gillespie, 2006).

*Intervention classification labels from Bulechek, G. M., Butcher, H. K., & Dochterman, J. M. (Eds.). (2008). *Nursing interventions classification (NIC)* (5th ed.). St Louis, MO: Mosby.

Evaluation

Nursing Actions

Patient Responses and Findings

Achievement of Outcomes

Review patient's exercise log at each visit.

She responds, "I make time to exercise because of this log. I hate missing a day and leaving a blank page; this represents failure. I want to succeed." Exercise log documents activity four times per week.

Patient reports enjoying exercise, as well as observing some personal benefits of exercise.

The exercise log is facilitating adherence to the exercise prescription.

Record weight, blood pressure, and pulse.

Weight, 95 kg. Resting heart rate between 80 and 85 beats per minute. Blood pressure, 146/86 mm Hg.

Improved cardiovascular effects of exercise:

- Heart rate is within normal range.
- Blood pressure is lower but not at expected range. Monitor blood pressure as patient continues to lose weight.

Ask patient if exercise is helping to lower fatigue level.

She responds, "At first, finding time to exercise was hard, but once I started feeling less tired and even less stressed, it was easy to integrate exercise into my daily activities."

Achieved improved activity tolerance with exercise.

► BOX 35-11 Promoting Exercise

Nurses can do the following to help patients participate in exercise:

- Educate patients about the importance of exercise in preserving health.
- Encourage patients to pace activities and increase speed and intensity gradually to avoid pain.
- Administer prescribed anti-inflammatory medications one to two hours before starting an exercise program.
- Encourage patients to balance rest and activity and to get plenty of sleep.
- Teach patients to use canes or walkers to assist with walking as needed.
- Encourage patients to choose smooth and even walking surfaces.
- Advise patients not to force joints past the point of resistance or pain.
- Teach patients to check legs and feet daily for redness, swelling, blisters, or broken skin.
- Teach patients to wear properly fitting shoes with nonslip soles.
- Encourage patients to walk with a companion or group so that exercise is socially rewarding.

For these patients, it is beneficial to reinforce that exercise can be incorporated in small amounts—as little as 10 minutes at a time. Activities such as taking a short walk at lunch or walking to the corner store instead of driving can help increase total exercise. A more active lifestyle can be promoted by taking the stairs instead of the elevator and parking farther from the entrance.

Other patients may benefit from a prescribed exercise and physical fitness program carefully designed to meet their needs and expectations. A comprehensive exercise prescription incorporates a combination of aerobic exercise, stretching and flexibility exercises, and resistance training. Aerobic exercise includes such activities as walking, running, bicycling, aerobic dance, jumping rope, and cross-country skiing. Recommended frequency of aerobic exercise is three to five times per week, or every other day. For a patient who prefers to exercise every day, recommend cross-training. For example, the patient may run one day and do yoga on the next day.

Stretching and flexibility exercises include active ROM exercises that allow for stretching of all muscle groups and joints. This form of exercise is ideal for warm-up and cool-down periods. Benefits include increased flexibility, improved circulation and posture, and an opportunity for relaxation.

Resistance training increases muscle strength and endurance and is associated with improved performance of daily activities and avoidance of injuries and disability. Formal resistance training includes weight training, but the same benefits can be obtained by performing ADLs such as pushing a vacuum cleaner, raking leaves, shovelling snow, and kneading bread. Some patients may use weight training to bulk up their muscles. However, the purpose of weight training from a health perspective is to develop tone and strength and to stimulate and maintain healthy bones (Katula et al., 2006).

Acute Care

Patients in acute care often have reduced activity tolerance or are immobile to varying degrees. Promoting activity and

► BOX 35-12 Recommendations for Exercise

Children 5-11 and Youths 12-17

Preamble

- Should be physically active as part of play, games, sports, transportation, recreation, physical education, or planned exercise in the context of family, school and community
- Activity can improve cholesterol levels, blood pressure, body composition, bone density, cardiorespiratory, musculoskeletal fitness, and aspects of mental health
- May be appropriate for children with a disability or medical condition

Guidelines

- At least 60 minutes of moderate- to vigorous-intensity physical activity daily
- Vigorous-intensity activities at least three days per week
- Activities that strengthen muscle and bone at least three days per week
- More daily physical activity provides greater health benefits

Adults 18-64

Preamble

- Can meet guidelines through planned exercise sessions, transportation, recreation, sports or occupational demands, in the context of family, work, volunteer and community activities
- Reduce the risk of premature death, coronary heart disease, stroke, hypertension, colon cancer, breast cancer, type 2 diabetes, osteoporosis, and improve fitness, body composition, and indicators of mental health
- Guidelines may be available for those who are pregnant, have a disability or medical condition

Guidelines

- At least 150 minutes of moderate- to vigorous-intensity aerobic physical activity per week, in bouts of 10 minutes or more
- Add muscle- and bone-strengthening activities using major muscle groups, at least two days per week

Adults 65 and Older

Preamble

- Should be achieved above and beyond the incidental physical activities accumulated in the course of daily living
- Following guidelines may reduce the risk of chronic disease and premature death, maintain functional independence and mobility, improve fitness, body composition, bone health, cognitive function, and indicators of mental health
- May be appropriate for older adults with frailty, a disability, or medical condition

Guidelines

- Accumulate at least 150 minutes of moderate- to vigorous-intensity aerobic physical activity per week in bouts of 10 minutes or more
- Add muscle- and bone-strengthening activities using major muscle groups at least two days per week
- Those with poor mobility should perform physical activities to enhance balance and prevent falls

Source: Adapted from Canadian Society of Exercise Physiology. (2011). *Canadian physical activity guide*. Retrieved from <http://www.csep.ca/english/view.asp?x=804>.

* BOX 35-13 FOCUS ON OLDER ADULTS

You should base an older patient's exercise program on individual assessment data (underlying conditions, medications, present activity level). Before starting an exercise program, consult the physician for exercise restrictions. Modification of the exercise program is based on the individual's responses. Instruct the patient as follows:

- It is never too late to begin an exercise program (Huddleston, 2006). However, remind patients to consult a health care provider before beginning an exercise program, particularly if a patient has heart or lung disease or other chronic illnesses.
- Recommend tai chi, a traditional Chinese conditioning exercise that increases balance and strength. This form of exercise has resulted in reduced fear of falling and an increased sense of well-being in older adults (Adler & Roberts, 2006). It has also been shown to improve balance and reduce falls (Leung et al., 2011).
- Improve joint mobility and enhanced circulation can be achieved simply by stretching and exaggerating movements during the performance of ADLs.
- Use correct body mechanics, wear appropriate clothing and footwear, and maintain sufficient hydration.
- Perform a gradual, extended exercise warm-up (e.g., 15 minutes) to maximize flexibility and decrease muscle injury.
- Begin at a low level (40% to 50% of predicted maximal heart rate; maximal heart rate is estimated as the number 220 minus patient's age), and follow gentle exercise progression.
- Avoid sudden twisting movements, rapid movements, and rapid transitions from one movement to the next.
- Maintain proper body alignment to minimize joint and muscle stress.
- Use stronger joints or larger muscle groups to decrease joint stress and pain.
- Avoid exercises that tax vision and balance.
- Avoid sustained isometric contractions of >10 seconds.
- Avoid exercise during acute viral infections.
- Stop exercising if cardiac dysrhythmias, angina, or excessive breathlessness occurs.
- Perform cool-down exercises until the heart rate returns to resting level to decrease postural hypotension and cardiac dysrhythmias.

Source: Adapted from Touhy, T., Jett, K., Boscart, V., and McCleary, L. (2012). *Ebersole & Hess' gerontological nursing and healthy aging* (1st Canadian ed.). Toronto: Elsevier Canada.

preventing the effects of **immobility** are paramount and described in Chapter 45. This chapter focuses on the way the nurse carries out the physical demands of nursing in such a way that the wellness of the nurse is promoted.

When working with patients who are immobile and physically dependent for mobility, nurses and other health care providers assist patients with turning and moving in bed, transferring between surfaces and walking. It is essential for nurses to utilize good body mechanics to reduce the risk of injury to themselves, their co-workers and their patients. In Ontario, over 50% of nurses who lost work time experienced musculoskeletal disorders—that is, injuries to the neck, shoulder, and back (Workers Health and Safety Centre, 2011). Whether you are assisting a patient from the bed to the chair, lifting a patient's limb, or teaching a patient to carry out ADLs

* BOX 35-14 CULTURAL ASPECTS OF CARE

Cultural influences play an important role in defining exercise and physical activity. Often, exercise is described relative to white, middle-class values. Immigrants may be more sedentary and less likely to join a fitness or golf club because they lack the financial means and social support or would not feel comfortable (Im & Choe, 2004). Certain cultures discourage involvement in organized recreational physical activities such as basketball and aerobics. In some cultures, ethnic dancing is a more acceptable activity than organized sports (Jain & Brown, 2001). Other cultures emphasize exercise through activities of daily living, such as walking, gardening, and prayer or meditation. As an example, people from Bangladesh view prayer as a structured form of exercise. Muslims value participation in community activities and may consider walking to the mosque part of their weekly exercise regime.

Implications for Practice

- Nurses must evaluate patterns of daily living and culturally prescribed activities before suggesting specific forms of exercise to patients.
- Nurses must help patients plan physical activities that are culturally acceptable.
- Exercise programs must be flexible and accommodate the patient's family, cultural, and community responsibilities.

efficiently, applying the principles of body mechanics is crucial to prevent injury. When providing patient care, incorporate your knowledge of physiological influences on body alignment and mobility.

Using principles of safe patient transfer and positioning during routine care activities also decreases work effort. To increase and reinforce the knowledge of colleagues and patients' families, teach them how to transfer and position patients properly.

The Canadian Centre for Occupational Health and Safety (2011) has published numerous guidelines related to ergonomic standards for preventing musculoskeletal injuries in the workplace. More than half of all back pain in health care settings is associated with manual lifting tasks (Workers Health and Safety Centre, 2011). Back injuries are often the direct result of improper lifting and bending. The most common back injury is strain on the muscle group around the lumbar vertebrae. Injury to this area affects the ability to bend forward, backward, and from side to side. The ability to rotate the hips and lower back is also decreased. Relying on body mechanics alone does not provide sufficient protection from musculoskeletal injuries that can occur when lifting or transferring patients (Waters et al., 2006). Although safe lifting guidelines are in widespread use, all of them acknowledge that no particular weight is absolutely safe to lift (Workers Health and

Safety Centre, 2011). Moreover, as has been stated, "The adult human form is an awkward burden to lift or carry. Weighing up to 200 pounds or more, it has no handles, it is not rigid, and is susceptible to severe damage if mishandled or dropped. When lying in a bed, a patient is placed inconveniently for lifting, and the weight and placement of such a load would be tolerated by few industrial workers" ("The nurse's load," 1965, p. 422).

Nurses need to be aware of good lifting techniques to protect themselves, those they supervise, and the patients being cared for. Before lifting, turning, or positioning a patient, assess the weight to be moved and what assistance the patient can provide. Do not attempt to lift a patient without assistance, unless the patient is a young child or a lightweight adult who is able to help while being moved. Often a second person and/or patient-handling equipment will be needed. Use mechanical lifts, friction-reduction devices, slide boards, and other handling aids available in your workplace (Worksafe BC, 2006). Many health care agencies have a "no-lift" policy, in which manual lifting of the whole or a large part of the weight of the patient by a health care worker is prohibited, except for in exceptional or life-threatening situations. Some agencies also utilize lift teams (Table 35-1).

Once the amount of assistance is determined and any necessary equipment is in place, the following steps should be followed:

1. Keep the weight to be lifted as close to the body as possible; this action places the object in the same plane as the lifter and close to the centre of gravity for balance.
2. Bend at the knees; this helps to maintain the centre of gravity and uses the stronger leg muscles to do the lifting (Figure 35-8).
3. Tighten abdominal muscles and tuck the pelvis; this provides balance and helps protect the back.
4. Maintain the trunk erect and knees bent so that multiple groups work together in a coordinated manner.
5. Avoid twisting. Twisting can overload the spine and lead to serious injury.

Nurse injuries are related not only to lifting. Many nursing activities involve bending and twisting and may cause injury. Examples of such activities are bathing, feeding, and dressing and undressing patients.

When an injury does occur, it is essential for the nurse to get immediate treatment for the injury (Box 35-15). The nurse must also report the injury to the appropriate supervisor and complete any necessary paperwork as per the health care facility's incident reporting system.

It is the responsibility of the nurse not only to implement existing safe handling policies within the workplace but also to advocate for enhancements to safety (Box 35-16). That includes identifying unsafe situations such as broken equipment or the improper techniques of others. It involves reviewing literature and government policy to remain current on best practices. The nurse must advocate for change within the workplace when safer options exist for the benefit of all staff and patients.

Restorative and Continuing Care

Restorative and continuing care involves implementing activity and exercise strategies to assist the patient regaining mobility and activity capacity after acute care is no longer needed. This type of restorative care is discussed in Chapter 45. Restorative and continuing care also includes activities and exercises

► **TABLE 35-1** Preventing Lift Injuries in Health Care Workers

Action	Rationale
When planning to move a patient, arrange for adequate help. If your institution has a lift team, use it as a resource.	A lift team is properly trained in techniques to prevent musculoskeletal injuries.
Use patient-handling equipment and devices, such as height-adjustable beds, ceiling-mounted lifts, friction-reducing slide sheets, and air-assisted devices.	These devices help to reduce the caregiver's muscular strain during patient handling.
Encourage patient to assist as much as possible.	This promotes patient's independence and strength but minimizes workload.
Keep back, neck, pelvis, and feet aligned.	Reduces risk of injury to lumbar vertebrae and muscle groups.
Avoid twisting.	Twisting increases risk of injury.
Flex knees; keep feet wide apart.	A broad base of support increases stability.
Position yourself close to patient (or object being lifted).	Reduces horizontal reach and stress on caregiver's back.
Use arms and legs (not back).	The leg muscles are stronger, larger muscles capable of greater work without injury.
Slide patient toward yourself, using a pull sheet or slide board.	Sliding requires less effort than lifting. A pull sheet minimizes shearing forces, which can damage patient's skin.
When transferring a patient onto a stretcher or bed, a slide board is more appropriate.	
The person with the heaviest load coordinates efforts of the team involved by counting to 3.	Simultaneous lifting minimizes the load for any one lifter.
Perform manual lifting as a last resort and only if it does not involve lifting most or all of a patient's weight.	Lifting is a high-risk activity that causes significant biochemical and postural stressors.

Figure 35-8 Body position for lifting. **A**, Incorrect. **B**, Correct.

► **BOX 35-15** Immediate Treatment of Soft Tissue Injuries

The most crucial period of time for treating soft tissue injuries is during the first 6 to 12 hours (Lewis et al., 2010). Basic treatment of soft tissue injuries is summarized by the acronym RICES:

- R:** Rest minimizes the potential for further damage to a joint already unstable because of injury.
- I:** Ice reduces pain threshold; it should not be applied for longer than 30 minutes at a time.
- C:** A wet elastic wrap is applied, with enough compression to hold ice in place.
- E:** Elevation of the injured part several centimetres above the heart facilitates venous return and reduces swelling.

* **BOX 35-16** EVIDENCE-INFORMED PRACTICE GUIDELINE

Promoting Safe Handling of Patients and Prevention of Injury to Nurses and Their Patients

- Know your health care facility's safety information and training concerning the transfer, positioning, and lifting of patients.
- Use recommended back safety guidelines to prevent musculoskeletal injuries.
- Use current research, standards, and guidelines regarding safe positioning and transfer of patients.
- Use "lift teams" and patient-handling equipment, such as mechanical lifts and transfer, to prevent injury to yourself and the patient.
- Advocate for the incorporation of evidence and guidelines into policies to promote a healthy work environment.

that restore and promote optimal functioning in patients with specific chronic illnesses, such as coronary heart disease (CHD), hypertension, chronic obstructive pulmonary disease (COPD), and diabetes mellitus (Box 35-17). Remaining active while living with chronic diseases improves outcomes, including prevention of complications, improved function, and enhanced quality of life. Given the degree of physical compromise individuals with one or more chronic diseases may experience, consultation with the patient's primary care provider and/or medical specialist is prudent prior to implementation of an exercise plan. There are patients whose chronic disease process may be so advanced that they are unable to participate in even the most modest of exercise programs.

Coronary Heart Disease (CHD). Activity and exercise have been shown to play a role in secondary prevention or recurrence of CHD. Cardiac rehabilitation is an integral part of the comprehensive care of patients who have been diagnosed with CHD. Nurses are involved in many aspects of cardiac rehabilitation and assist patients in developing exercise programs that fit their needs and levels of functioning. Increased

BOX 35-17 RESEARCH HIGHLIGHT

Energy Requirements of Tai Chi

Research Focus

Developing alternative exercise strategies for patients with very low functional capacities is a challenge because of the increased risk for complications and injuries. Tai chi c'hih, a modified version of tai chi, may be an approach to health promotion in older adults and in patients with chronic illnesses.

Research Abstract

The purpose of the study conducted by Li et al. (2004) was to determine the energy cost of tai chi c'hih, which is a form of exercise consisting of a series of slow, balanced movements and breathing. The objective of this study was to measure the energy costs and cardiovascular effects of tai chi c'hi to assist in the planning of a safe exercise regime for patients with very low energy reserves. Twenty-six adults participated in the completion of surveys to estimate functional capacity and exercise participation, in a select series of nine tai chi c'hih movements, and in oxygen consumption testing during the exercise program. The results of the study indicated that the energy requirements for this alternative form of exercise were comparable with low-level exercises suitable for people with low exercise tolerance.

Evidence-Informed Practice

- Before initiating exercise, patients should consult a health care provider.
- Encouraging patients with chronic illnesses to exercise has the potential to maintain and improve activity tolerance.
- Tai chi c'hih promotes feelings of relaxation and increased energy, thus making it an ideal alternative form of exercise for patients with chronic illnesses.

physical activity appears to benefit individuals with myocardial infarction, angina pectoris, or heart failure, as well as those who have had a coronary artery bypass graft or percutaneous transluminal coronary angioplasty. Patients with CHD benefit from exercise and activity and can experience reduced mortality and morbidity, improved quality of life, increased psychological well-being, improved left ventricular function, increased functional capacity, and decreased blood lipids (Conroy et al., 2005; Villareal et al., 2006).

Hypertension. Exercise is instrumental in the reduction of systolic and diastolic blood pressure readings. Low-to moderate-intensity aerobic exercise (e.g., brisk walking, bicycling) appears to be the most effective exercise for lowering blood pressure, whereas weight training and high-intensity aerobics seem to have minimal benefits (Gillespie, 2006; Huddleston, 2006).

Chronic Obstructive Pulmonary Disease (COPD). Individuals with COPD should be encouraged to remain physically active. Some patients are fearful of participating in exercise because of the potential of worsening dyspnea (difficulty breathing). This aversion to physical activity sets up a progressive deconditioning in which minimal physical exertion results in dyspnea. Pulmonary rehabilitation is a beneficial therapeutic tool to help patients with COPD reach an optimal level of functioning. Patients can be taught specific breathing

techniques to reduce the work of breathing that can be applied in times of anxiety or stress when inefficient breathing patterns appear (O'Donnell et al., 2008).

Diabetes Mellitus. Along with diet, glucose monitoring, and medication, exercise is an important component in the care of patients with diabetes mellitus. Individuals with type 1 diabetes are encouraged to exercise because exercise leads to improved cardiovascular fitness and psychological well-being. You can instruct the patient with type 1 diabetes about certain risks and precautions regarding exercise. Instruction should include the need for a pre-exercise physical examination and precautions to monitor blood glucose immediately before and after exercise. You also can instruct patients to perform low- to moderate-intensity exercises, to carry a concentrated form of carbohydrates (e.g., sugar packets, hard candy), and to wear a medical alert bracelet. Patients with type 2 diabetes who decide to participate in a regular program of exercise should incorporate low-intensity warm-up and cool-down periods, should include aerobic exercise at 50% to 75% of maximal oxygen uptake, and should exercise for 150 minutes per week. They should also participate in resistance exercise three times per week (Canadian Diabetes Association, 2008).

❖ Evaluation

Patient Care

With regard to activity and exercise, measure the effectiveness of nursing interventions by the success in meeting the patient's expected outcomes and goals of care. The patient is the only one who will experience the effectiveness and benefits of activity and exercise (Figure 35-9). To evaluate the effectiveness of nursing interventions in enhancing activity and exercise, make comparisons with baseline measures that include pulse, blood pressure, strength, endurance, and psychological well-being. Compare actual outcomes with expected outcomes to determine the patient's health status and progression. Continuous evaluation helps to determine whether new or revised therapies are required and whether new nursing diagnoses have developed.

Patient Expectations

To evaluate the patient's perception of nursing care related to activity and exercise, you must first have assessed the patient's perspective on what is most important and the patient's expectations of the health care team. Working closely with the patient will enable you to identify goals and strategies that can be met realistically within the limits of the patient's priorities, capabilities, and health treatment (Box 35-18). Because the outcome you consider to be acceptable or anticipated may be different from that of the patient and family members, it is important to ask patients if their expectations of care have been met.

❖ KEY CONCEPTS

- Exercise is physical activity for the purpose of conditioning the body, improving health, and maintaining fitness, or it may be used as a therapeutic measure.
- Careful attention to body mechanics and use of appropriate equipment is critical in the prevention of musculoskeletal injuries.
- Activity tolerance is the kind and amount of exercise or work that a person is able to perform.
- Physiological, emotional, and developmental factors influence the patient's activity tolerance.

Figure 35-9 Critical thinking model for activity and exercise evaluation.

- The best program of physical activity includes a combination of exercises that produce different physiological and psychological benefits.
- Coordinated body movement to move, lift, bend, stand, sit, lie down, and complete daily activities requires integrated functioning of the skeletal system, skeletal muscles, and nervous system.
- Muscles primarily associated with movement are located near the skeletal region, where movement results from leverage, which is characteristic of the upper extremities.
- Coordination and regulation of muscle groups depend on muscle tone and activity of antagonistic, synergistic, and anti-gravity muscles.
- Balance is assisted by nervous system control in the cerebellum and by inner ear function.
- Body balance is achieved when a wide base of support exists, the centre of gravity is within the base of support, and the centre of gravity is vertically aligned with the base of support.
- Developmental changes, behavioural aspects, environmental issues, cultural and ethnic influences, and family and social support affect the patient's perception of and motivation to engage in physical activity and exercise.
- Ability to engage in normal physical activity and exercise depends on intact and functioning nervous and musculoskeletal systems.
- Use the nursing process to provide care for patients who are experiencing or are at risk for activity intolerance and impaired physical mobility.

BOX 35-18 NURSING STORY

Activity and Exercise

I have been in nursing for over 40 years. For more than 30 years of that time, before moving into teaching, I worked as a hospital staff nurse providing direct care to patients. I worked mainly in areas where patients were unable to assist themselves very much, such as in the birthing and critical care units. As is the case with most nurses, the wear and tear of lifting, turning, and transferring patients took a toll on my body, primarily on my back, knees, and feet. But for as long as it was part of my role, I was able to do work.

Several years later, after I began teaching a nursing fundamentals course, my physical activity related to nursing consisted of demonstrating fundamental skills in the laboratory setting and of providing assistance to students with their practice. During my fifth year of teaching that course, I was taken by surprise at how difficult I found it to lift, position, or transfer my volunteer "patients," and at how extremely tired and sore I was at the end of each day. What was happening to me?

Upon reflection, I realized that two factors were involved. The first was normal change resulting from aging: the decrease in strength and endurance that occurs after age 40 among women. The second factor was the relatively sedentary lifestyle I had led since I had left bedside nursing. Mine was a classic case of functional decline from disuse, a major concern as aging occurs. As I thought further about it, I remembered that I had noticed groceries becoming heavier and stair climbing feeling more difficult. At the rate I was changing, I had little hope of maintaining my independence well into old age. In the shorter term, if I expected to keep teaching for a few more years, I would need to do something about my fitness level quickly!

My strategies? To use my gym membership (neglected for months and never attended routinely) four times per week from June through August and at least three times per week throughout the academic year, and to walk for no less than 30 minutes every day. No more avoiding stairs, either! I decided to walk up one floor and down two or three until that became easier and then increase stair climbing from there.

How will I know whether my plan has been effective? Although I don't expect to be as strong as I once was as a clinical nurse, I will be able to accomplish my teaching activities and my normal daily routines effortlessly, with minimal backaches and energy to spare.

Although it was a shock to recognize that aging had affected my personal and professional life, the ingrained nursing habits of reflection and of establishing goals helped me feel confident that I could manage them.

- After identifying nursing diagnoses, plan and implement interventions to increase activity and exercise, in collaboration with the patient when possible.
- Range-of-motion (ROM) exercises incorporated into daily activities can include one or all of the body's joints.

❖ CRITICAL THINKING EXERCISES

1. Mr. Neel is a 66-year-old man who retired from his job as a grocery store manager last year. He has hypertension, for which he takes hydrochlorothiazide, and is overweight. He is interested in beginning a regular exercise routine. What assessments should the nurse conduct prior to the patient starting an exercise program? What directions or guidelines would you give him?
2. Mrs. Wong has quadriplegia, weighs 72 kg, and requires total care. Her family has decided to care for her at home. As her

nurse, you are responsible for instructing the family on several aspects of Mrs. Wong's care. Develop a list of basic principles that describes safe lifting and positioning to protect Mrs. Wong's family members from injury.

❖ REVIEW QUESTIONS

1. Nurses must know and practise safe lifting, positioning, and transfer techniques in order to
 1. Increase their muscle strength
 2. Restore optimal patient functioning
 3. Reduce the risk of injury
 4. Assess the body alignment of patients
2. Proprioception is
 1. Awareness of the position of the body
 2. Needed for antigravity
 3. Located within the semicircular canals
 4. The individual's perception of movement at a joint
3. The Canadian Society of Exercise Physiology's 2011 *Canadian Physical Activity Guidelines* recommend that adults get
 1. 30 to 60 minutes of moderate intensity aerobic physical activity per day
 2. 60 to 120 minutes of moderate physical activity per week
 3. 150 minutes of moderate to vigorous intensity aerobic physical activity per week
 4. 30 minutes of moderate to vigorous intensity aerobic physical activity per day
4. Older adults are at greater risk for falls and injuries partly because
 1. They may take smaller steps, decreasing their base of support
 2. Their centre of gravity shifts toward the anterior
 3. They tend to walk more quickly, with wide strides
 4. Total bone mass decreases
5. Patients are more open to developing an exercise program if they
 1. Have been diagnosed with a chronic disease such as diabetes
 2. Are ordered by a physician to begin an exercise program
 3. Have had a family member request that they exercise
 4. Are at the stage of being ready to change their behaviour
6. Children becoming increasingly less physically active outside of school has resulted in
 1. An increase in juvenile arthritis
 2. An increase in obesity
 3. Improved school attendance and grades
 4. An increase in school-based fitness activities
7. The nurse's role in ensuring safe patient handling includes
 1. Using the health care agency's mechanical lift when previously trained on similar lifts
 2. Performing patient transfers alone, because there is no one else available to help
 3. Allowing other nurses to complete activities which appear unsafe
 4. Reporting unsafe patient handling equipment or situations to a supervisor

❖ RECOMMENDED WEB SITES

Active Living Alliance for Canadians with a Disability: <http://www.ala.ca/content/home.asp>

This organization is an alliance of individuals, agencies, and national associations that together promote, support, and enable Canadians with disabilities, across all settings and environments, to lead active and healthy lives.

Canadian Centre for Activity and Aging: <http://www.uwo.ca/actage/>

The centre is a research and community resource institution whose mandate is to investigate the interrelationship of physical activity and aging and to develop strategies, based on research, to promote the independence of older adults.

Canadian Fitness and Lifestyle Research Institute: <http://www.cflri.ca/>

The institute addresses the well-being of Canadians through research on and communication of information about physically active lifestyles to the public and private sectors.

Canadian Society for Exercise Physiology (CSEP): www.csep.ca
CSEP is the principal body for physical activity, health and fitness research, and personal training in Canada. It provides high-quality research, education, and training related to exercise physiology and science. It is the gold standard of health and fitness professionals and is dedicated to getting Canadians active safely by providing customized and specialized physical activity and fitness programs, as well as guidance and advice based on extensive training and evidence-based research.

Fitness Vancouver: <http://www.fitnessvancouver.ca/>

This Web site's Exercise Library contains an abundance of clearly described and well-illustrated exercises that any nurse could use to establish a fitness program.

Health Promotion Online: <http://www.phac-aspc.gc.ca/hp-ps/index-eng.php>

Health Canada maintains this Web site, which contains many useful health promotion resources and guides that will aid health care providers and community leaders in encouraging Canadians to take a more active role in improving their health.

Public Health Agency of Canada: <http://www.phac-aspc.gc.ca/chn-rcs/index-eng.php>

The role of this federal agency is to protect the health and safety of Canadians, focusing on preventing chronic diseases, preventing injuries, and responding to public health emergencies such as outbreaks of infectious diseases.

Public Services Health & Safety Association: www.healthandsafetyontario.ca

Public Services Health & Safety Association provides Ontario's public-service sector with information and strategies about how to achieve safer and healthier work environments for their workers. Regional and on-site prevention training, risk assessment, and safety consulting are used to identify and reduce workplace risks and hazards while preventing workplace injuries, illness, and disease.

Rationales for the Review Questions appear at the end of the book.

Safety

Original chapter by Marinetta DeMoss, RN, MSN

Canadian content written by Daria Romaniuk, RN, PhD

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Describe how the unmet basic physiological needs of oxygen, nutrition, temperature, and humidity can threaten patients' safety.
- Discuss the specific risks to safety related to each developmental stage.
- Discuss strategies to maintain nurse safety.
- Discuss the least-restraint approach.
- Describe the four categories of risks in a health care agency.
- Describe assessment activities designed to identify patients' physical, psychosocial, and cognitive statuses as they pertain to patients' safety status.
- Identify nursing diagnoses associated with risks to safety.
- Develop care plans for patients whose safety is threatened.
- Describe nursing interventions specific to patients' age for reducing the risk of falls, fires, poisonings, and electrical hazards.
- Describe methods to evaluate interventions designed to maintain or promote safety.

Safety, often defined as freedom from psychological and physical injuries, is a basic human need that must be met. Health care provided in a safe manner and in a safe community environment is essential for a patient's survival and well-being. While incorporating critical thinking skills when following the nursing process, you are also responsible for assessing the patient and the environment for safety hazards as well as for planning and intervening appropriately to maintain a safe environment. By paying attention to patient safety, you are not only functioning as a provider of safe care but also as an active participant in health promotion. Nurses must also ensure their own safety as they provide patient care.

Scientific Knowledge Base

Environmental Safety

A patient's **environment** includes the physical and psychosocial factors that influence or affect the life and survival of that patient. This broad definition of environment crosses the continuum of care for settings in which you and patients interact (e.g., the home, community centre, school, clinic, hospital, and long-term care facility). Safety in health care settings reduces the incidence of illness and injury, shortens the length of treatment or hospitalization,

improves or maintains a patient's functional status, and increases the patient's sense of well-being. A safe environment affords protection to the staff as well, allowing them to function at an optimal level. A safe environment is one in which basic needs are met, physical hazards are reduced, the transmission of pathogens is reduced, sanitation is maintained, and pollution is controlled. In addition, in a safe environment, a plan is in place to respond to a possible terrorist attack.

Basic Needs. Physiological needs, which include sufficient oxygen and nutrition and the optimal temperature and humidity, influence a person's safety.

Oxygen. Be aware of factors in a patient's environment that decrease the amount of available oxygen. A furnace that is not properly vented or a car left running inside a closed garage may introduce carbon monoxide into the environment.

Carbon monoxide is a colourless, odourless, poisonous gas produced by the combustion of carbon or organic fuels. It binds strongly with hemoglobin, preventing the formation of oxyhemoglobin and thus reducing the supply of oxygen delivered to tissues (see Chapter 38). Exposure can cause nausea, headache, drowsiness, confusion, loss of consciousness, and death (Technical Standards and Safety Authority, 2004). Carbon monoxide detectors can be purchased for home use.

Nutrition. Meeting nutritional needs adequately and safely requires environmental controls and knowledge. In the home, the patient needs a refrigerator with a freezer compartment to keep perishable foods fresh. An adequate clean water supply is needed for drinking and to wash dishes and fresh produce. Provisions for garbage collection are necessary to maintain sanitary conditions.

Foods that are inadequately prepared or stored, or are subject to unsanitary conditions, increase a patient's risk for infections and food poisoning. Bacterial food infections result from eating food contaminated by bacteria such as *Escherichia coli* and *Salmonella*, *Shigella*, or *Listeria* organisms. **Food poisoning** is caused by the ingestion of bacterial toxins produced in food; staphylococcal and clostridial bacteria are the most common causes. Although most foodborne diseases are bacterial, the hepatitis A virus is spread by fecal contamination of food, water, or milk (Health Canada, 2004).

In illnesses caused by bacterial contamination, the onset of symptoms may be very rapid or take a week or even longer. For hepatitis A, the average incubation period is 28 to 30 days (Health Canada, 2004). Preventive measures include thorough handwashing before handling food, adequate cooking, and the proper storage and refrigeration of perishable foods.

For consumer protection, commercially processed and packaged foods are subject to the provisions of the *Food and Drug Act*, which regulates the manufacture, processing, and distribution of foods, drugs, and cosmetics. The Act protects consumers from the sale of impure or dangerous substances. Ensuring safe food supplies for Canadians is a joint effort between Health Canada, the Canadian Food Inspection Agency, and provincial, territorial, and municipal organizations.

Temperature and Humidity. The comfort zone for environmental temperature varies among individuals, but the usual comfort range is between 18.3°C and 23.9°C. Temperature extremes that frequently occur during the winter and summer affect not only comfort and productivity but also safety.

Exposure to severe cold for prolonged periods may cause frostbite and hypothermia. Frostbite occurs when a surface

area of the skin freezes as a result of exposure to extremely cold temperatures. **Hypothermia** occurs when the core body temperature is 35°C or below (see Chapter 30). Older adults; the young; patients with cardiovascular conditions; patients who have ingested drugs, alcohol, or other substances in excess; and the homeless are at high risk for hypothermia.

Exposure to extreme heat can raise the core body temperature, resulting in heatstroke or heat exhaustion. Chronically ill patients, older adults, and infants are at greatest risk for injury from extreme heat. These patients should avoid extremely hot, humid environments.

The relative humidity of the air in the environment may affect a patient's health and safety. **Relative humidity** is the amount of water vapour in the air compared with the maximum amount of water vapour that the air could contain at that temperature. The comfort zone varies from person to person, but most individuals are comfortable when the humidity is between 60% and 70%. Increasing the environmental humidity can have therapeutic benefits for patients with upper respiratory tract infections because humidity helps to liquefy pulmonary secretions and improve breathing. It is important to follow the manufacturer's directions regarding the cleaning and maintenance of home humidifiers to prevent water contamination.

Physical Hazards. Physical hazards in the environment place patients at risk for accidental injury and death. In Canada, unintentional injuries are the leading cause of death for individuals between the ages of 1 and 34 years (Public Health Agency of Canada, 2005) and are also a major cause of disability. Specific causes of injury and death include poisoning, suffocation, drowning, fires, burns, and machinery accidents. Among adults aged 65 and over, falls are the most common cause of unintentional injury (Canadian Institute for Health Information [CIHI], 2010). Many physical hazards, especially those contributing to falls, can be minimized through adequate lighting, the reduction of obstacles, and the implementation of security measures.

Lighting. Adequate lighting reduces physical hazards by illuminating the areas in which a person moves and works. Outside the home, all walkways should have adequate lighting. Outdoor lighting also helps protect the home and its inhabitants from crime. Well-lit garages, walkways, and doorways discourage intruders from entering or lurking on the premises.

Inside the house, halls, staircases, and individual rooms should be adequately lit so that residents can safely carry out activities of daily living. Night lights in dark halls, bathrooms, and the rooms of children, older adults, and guests help maintain safety. Glare is a major problem for older adults; therefore, strategies to minimize glare, such as the use of blinds and shades, are recommended (Ebersole et al., 2008).

Obstacles. Injuries in the home frequently result from tripping over or coming into contact with common household objects, including small rugs on the stairs and floor, wet spots on the floor, and clutter on surfaces. The risk of falls from obstacles is present for all age groups; however, it is greatest for older adults. Falls are usually the result of a combination of intrinsic risk factors (e.g., illness, drug therapy, or alcohol use) and extrinsic or environmental factors. In some cases, an obstacle or extrinsic factor may be the only cause of a fall. Intrinsic factors may be difficult to modify or eliminate, but extrinsic factors are usually easily removed.

Fire. Fire kills, on average, eight Canadians each week, and 73% of these deaths occur as a result of fire in the home (Fire Prevention Canada, 2011). Most of these deaths are due to smoke inhalation. The most common causes of fire are careless smoking and cooking accidents.

Poisoning. A **poison** is any substance that impairs health or destroys life when ingested, inhaled, or otherwise absorbed by the body. Individuals can be at risk for poisoning from substances such as cleaning agents, medications, and plants. Specific antidotes or treatments are available for only some types of poisons. The capacity of body tissue to recover from the poison determines the reversibility of the effect. Poisons can impair the respiratory, circulatory, central nervous, hepatic, gastrointestinal (GI), and renal systems of the body.

Lead poisoning from various sources is an important safety concern. Although Canadian regulations have restricted the lead content of paint since 1976, older homes may still have high lead levels because of old paint. Lead may also be found in contaminated water systems and in household articles such as vinyl blinds and candles. Exposure to lead may occur through oral ingestion, inhalation, or the skin. Fetuses, infants, and children are more vulnerable to lead poisoning than adults because lead is more easily absorbed into their growing bodies. As well, small children are more sensitive to the damaging effects of lead. Exposure to excessive levels of lead can lead to vomiting, headaches, anemia, weight loss, poor attention span, slowed speech development, and learning difficulties (Health Canada, 2009).

Security. An insecure home places a patient at risk for injury or burglary. Inadequate locks on doors and windows make the home susceptible to intruders. A lack of attention to personal safety can place the patient at risk for injury away from home as well, for example, when walking or driving after dark.

Transmission of Pathogens. A **pathogen** is a microorganism capable of producing an illness. Medical asepsis reduces the transfer of organisms (see Chapter 32). One of the most effective methods of limiting pathogen transmission is the aseptic practice of hand hygiene. Patients must be instructed in proper hand-hygiene techniques and encouraged to use them frequently in the home and hospital.

The transmission of disease from person to person can also be reduced, and in some cases prevented, by immunization. **Immunization** is the process by which resistance to an infectious disease is produced or augmented. Active immunity is acquired by injecting a small amount of attenuated (weakened) or dead organisms or modified toxins from the organism (toxoids) into the body. Passive immunity occurs when antibodies produced by other individuals or animals are introduced into a person's bloodstream for protection against a pathogen.

Human immunodeficiency virus (HIV)—the pathogen that causes acquired immunodeficiency syndrome (AIDS)—and hepatitis B virus are transmitted through blood and other body fluids.

Substance abusers frequently share syringes and needles; this practice increases the risk of acquiring these viruses. Safer sex practices (see Chapter 26), including the correct use of condoms and engaging in monogamous relationships, reduce the risk for both of these diseases and for other sexually transmitted infections. The hepatitis C virus is bloodborne and can be spread through injection drug use as well as with body piercing or tattooing. You maintain your own safety as well as

that of patients and other people in the health care setting when you use standard precautions and routine practices during care for all patients to prevent the spread of infection and contact with blood and body fluids (see Chapter 32).

At the community level, the transmission of disease is also controlled through the adequate disposal of human waste through the proper construction and repair of sewers and drains. Rodent and insect control (e.g., spraying for mosquitoes) is also necessary to reduce the transmission of disease.

Pollution. A healthy environment is free of pollution. A **pollutant** is a harmful chemical or waste material discharged into the water, soil, or air. People commonly think of pollution only with regard to air, land, or water pollution, but excessive noise can also be a form of pollution that presents health risks. **Air pollution** is the contamination of the atmosphere with a harmful chemical. Prolonged exposure to air pollution increases the risk of pulmonary disease. In urban areas, industrial waste and vehicle exhaust are common contributors to air pollution. Cigarette smoke is a common cause of air pollution. **Land pollution** can be caused by the improper disposal of radioactive and bioactive waste products (e.g., dioxin).

Water pollution is the contamination of lakes, rivers, and streams, usually by industrial pollutants. Water-treatment facilities filter harmful contaminants from the water, but these systems can contain flaws. If water becomes contaminated, the public must use bottled or boiled water for drinking and cooking. Flooding frequently causes damage to water-treatment stations, which also necessitates the use of bottled or boiled water. Another hazard is the contamination of water with nitrates, chemicals made up of nitrogen and oxygen. These chemicals occur naturally in soil and may also be added through the use of fertilizers; contamination of well water may occur when nitrates leach out of the soil into the water (Government of Saskatchewan, 2008). Nitrates pose a hazard to our health, particularly for pregnant women and infants, who are more susceptible to methemoglobinemia, an illness that occurs when ingested nitrates are converted to nitrites in the body (Government of Saskatchewan, 2008). The nitrites disrupt the oxygen-carrying capacity of the blood, causing cyanosis, shortness of breath, and fatigue. Routine testing of municipal water supplies for nitrates ensures that levels are maintained within the accepted limit of less than 10 mg/L nitrate-nitrogen. However, you may need to educate individuals with private wells about arranging for annual testing of their water (Government of Saskatchewan, 2008).

Noise pollution occurs when the noise level in an environment becomes uncomfortable to the inhabitants of the environment. Noise levels are measured in units of sound intensity called decibels. Tolerance for noise varies from individual to individual and is influenced by health status. Irreversible hearing loss may result from constant exposure to high sound intensity. Patients working in environments with high noise levels should wear protective devices to reduce hearing loss (Figure 36-1). Adolescents should limit their exposure to intense noise such as that encountered at rock concerts.

A health care facility can also be polluted by noise. The sounds of machines, people talking, intercoms, and paging systems can create increased noise levels. Even when the noise level is not high enough to affect hearing acuity, it can produce a syndrome called sensory overload, which is a marked increase in the intensity of auditory and visual stimuli. It disrupts processing of information, and the patient no longer perceives the environment in a meaningful way (see Chapter 47).

Figure 36-1 Protective device to reduce hearing loss.

Terrorism. A more recent potential environmental health threat is the possibility of a terrorist attack. The terrorist attacks in the United States on September 11, 2001 raised awareness of this threat for Canadians. If a terrorist health threat were to occur in Canada, Health Canada would work with provincial, territorial, and local health officials to address the situation. Hospitals are one of several components of a community's emergency response plan (Christian et al., 2005). You must be prepared through education and training to respond to an attack by taking the necessary steps to participate in your agency's role in the community's emergency management plan.

Nursing Knowledge Base

In addition to being knowledgeable about the environment, you must be familiar with a patient's developmental level; mobility, sensory, and cognitive statuses; and lifestyle choices. You must also be aware of common safety precautions and of the special risks to safety that are found in agency settings.

Risks at Developmental Stages

A patient's developmental stage presents specific threats to safety. Patients throughout all developmental stages may be subject to abuse. Child abuse, domestic violence, and abuse of older adults are serious threats to safety. These topics are discussed in Chapters 23, 24, and 31.

Infants and Children. Unintentional injuries are the leading cause of death in Canadian children between the ages of 1 and 14 years; each year 1 of every 230 children is hospitalized for treatment of unintentional injuries (Safe Kids Canada, 2007). The nature of the injuries sustained is related to normal growth and development. Small children are curious and trusting of their environment and do not perceive themselves to be in danger. The incidence of poisoning is highest in late infancy and toddlerhood because of children's increased level of oral activity and growing ability to explore the environment. Toddlers and preschoolers, who are attracted to water but do not perceive its dangers, are at a greater risk for drowning. Childhood injuries are also reflective of adults' perceptions of the causes of accidents and their ability to prevent them. For example, the incorrect use of vehicle restraints for children aged 5 to 14 places these children at greater risk of death from injuries sustained in motor vehicle accidents (the leading cause

BOX 36-1

Changes Associated With Aging That Increase the Risk of Accidents

Musculoskeletal Changes

Muscle strength and function decrease, joints become less mobile, bones are more brittle due to osteoporosis, postural changes (e.g., kyphosis) are common, and range of motion is limited.

Nervous System Changes

All voluntary or automatic reflexes slow to some extent, the ability to respond to multiple stimuli decreases, and sensitivity to touch is decreased.

Sensory Changes

Peripheral vision and lens accommodation decrease, lenses may develop opacity (cataracts), the stimuli threshold for light touch and pain increases, the transmission of hot and cold impulses is delayed, and hearing is impaired as high-frequency tones become less perceptible.

Genitourinary Changes

Nocturia and occurrences of incontinence increase.

Source: Adapted from Ebersole, P., Hess, P., Touhy, T. A., Jett, K., & Luggen, A. (2008). *Toward healthy aging: Human needs and nursing response* (7th ed.). St Louis, MO: Mosby.

of death from injury in this age group) (Safe Kids Canada, 2007).

Adolescents. As children enter adolescence, they develop greater independence and begin to develop a sense of identity and their own values. Adolescents start to separate emotionally from their families, and peers generally have a stronger influence on them. The struggle for identity may cause a teenager to experience shyness, fear, and anxiety, with resulting dysfunction at home or school. In an attempt to relieve the tensions associated with physical and psychosocial changes, as well as peer pressures, adolescents may begin to act impulsively and engage in risk-taking behaviours such as smoking and substance use. In addition to the health risks posed by nicotine and other substances (e.g., alcohol, drugs, glue), the ingestion of such substances increases the incidence of accidents such as drowning and motor vehicle accidents.

Adults. Threats to an adult's safety are frequently related to lifestyle habits. For example, a patient who consumes excessive alcohol is at greater risk for motor vehicle accidents. A long-term smoker has a greater risk of cardiovascular and pulmonary diseases. Likewise, an adult experiencing a high level of stress is more likely to have an accident or illnesses such as headaches, GI disorders, and infections.

Older Adults. The physiological changes that occur during the aging process increase a patient's risk for injury (Box 36-1). Changes in vision, hearing, mobility, reflexes, circulation, and the ability to make quick judgements predispose older adults to falls (see Chapter 24). When a patient is hospitalized, confusion, multiple medical problems, medications, immobility, urinary urgency, age-related sensory changes, postural instability, and an unfamiliar environment further contribute to the risk of falls (Meiner & Leuckenotte, 2006). Certain disease states common to older adults, such as arthritis and cerebrovascular accidents, also increase the chances of injury. In 2007–08, unintentional falls were the most common cause of injury in adults aged 65 years and older, with 70% of injuries

in this age group caused by falls (Canadian Institute for Health Information [CIHI], 2010). Patients most often fall while transferring from beds, chairs, and toilets; while getting into or out of a bathtub; by tripping over carpet edges or doorway thresholds; by slipping on wet surfaces; and while descending stairs. Icy walkways and obstacles in the yard are also common causes of outdoor falls in older adults.

Individual Risk Factors

Other risk factors posing threats to safety are lifestyle, impaired mobility, sensory or communication impairment, and a lack of safety awareness.

Lifestyle. Lifestyle can increase safety risks. Individuals who drive or operate machinery while under the influence of chemical substances, who work at inherently dangerous jobs, or who are risk takers are at greater risk of injury. In addition, individuals experiencing stress, anxiety, fatigue, or alcohol or drug withdrawal and those taking prescribed medications may be more accident prone. These patients may also be too preoccupied to notice a source of potential accidents, such as cluttered stairs or a road intersection.

Impaired Mobility. Impaired mobility due to muscle weakness, paralysis, or poor coordination or balance is a major factor in patient falls. Immobilization predisposes a patient to additional physiological and emotional hazards, which can in turn further restrict mobility and independence.

Sensory or Communication Impairment. Patients with visual, hearing, tactile, or communication impairment, such as aphasia or a language barrier, are at greater risk for injury. Such patients may not be able to perceive a potential danger or express their need for assistance (see Chapter 47).

Lack of Safety Awareness. Some patients are unaware of safety precautions, such as keeping medicine or poisons away from children or observing the expiration date on food products. A complete nursing assessment, including a home inspection, helps you identify the patient's level of knowledge regarding home safety so that deficiencies can be corrected with an individualized nursing care plan.

Risks in the Health Care Agency

You must also be aware of specific risks to your patients and to yourself that exist in health care agencies.

Workplace Risks. Various forms of chemicals used in health care settings are a source of environmental risk for both the patient and the health care worker. Chemicals such as mercury and those found in some medications, anaesthetic gases, cleaning solutions, and disinfectants are potentially toxic if ingested or inhaled. The **Workplace Hazardous Materials Information System (WHMIS)** sets the standards for the control of hazardous substances in workplaces across Canada (Health Canada, 2008). A hazardous substance is any product or material that could cause physical or medical problems. WHMIS consists of three main elements: worker education programs, cautionary labelling of products, and the provision of **Material Safety Data Sheets (MSDSs)**. Cautionary labels display the product's physical and health hazards and safety and first aid measures, and identify the types of hazard that the product presents (Figure 36-2). MSDSs provide detailed information about the substance, any health hazards imposed, precautions for safe handling and use, and steps to take if the substance is released or spilled. You must understand WHMIS labelling requirements and be aware of the location of MSDSs where you work.

Controlling the spread of infection through the consistent use of routine practices maintains the safety of patients, staff, and visitors (see Chapter 32). The importance of these measures was illustrated during the outbreak of severe acute respiratory syndrome (SARS) in Toronto in 2003. The illness began with one individual admitted to an emergency department and spread to several patients and staff before its infectious nature was recognized and precautions were instituted.

Violence may be directed toward nurses from patients or patients' family members. Factors that can contribute to abusive situations include insufficient staffing levels, violation of patients' personal space due to lack of privacy, and the provision of care that requires close physical contact (Canadian Nurses Association, 2005). Violence toward nurses can take the form of threats, intimidation, and physical behaviours such as throwing objects (College of Registered Nurses of Nova Scotia, 2007). You should not tolerate abuse from patients; seek assistance from co-workers to help you manage abusive situations. If you perceive that you are in danger and that the risk to you is greater than the risk to the patient if you withdraw care, you should remove yourself from the situation and seek assistance from other team members (College of Nurses of Ontario, 2009a). You should report all incidents of workplace violence, as this is essential to the development of effective strategies to reduce such occurrences.

Risks to Patient Safety. Specific risks to a patient's safety within the health care environment include falls, patient-inherent accidents, procedure-related accidents, and equipment-related accidents. Assess for these four potential problem areas and take steps to prevent or minimize accidents. When an accident occurs, file an incident report (also called *adverse occurrence report*). This report is a confidential document that completely describes any patient accident occurring on the premises of a health care agency (see Chapter 15). The report documents the accident, the patient assessment, and interventions carried out for the patient. In addition to completing the incident report, you must objectively document the incident in the patient's medical record. Because this is a confidential document, the completion of the incident report should not be mentioned in the medical record because this eliminates the health care agency's protective clause.

Falls. Falls account for up to 90% of all reported incidents in hospitals. In addition to age, a history of previous falls, gait disturbance, balance and mobility problems, postural hypotension, sensory impairment, urinary and bladder dysfunction, use of medications, and certain medical diagnostic categories (e.g., cancer and cardiovascular, neurological, and cerebrovascular diseases) increase the risk of falling. One of the more common factors precipitating a fall is a patient's attempt to get out of bed to use the toilet. Hip fractures are among the most serious fall-related injuries. Between April 2003 and March 2006, the rate of hip fracture in Canadian seniors during admission to hospital was close to one in 1000 (CIHI, 2007). Older adults with a hip fracture may have a long period of recovery and may not be able to return to their previous level of functioning, even losing their ability to live independently (SMARTRISK, 1998). Falls that result in injuries can extend a patient's length of stay in the health care environment, placing the patient at a greater risk for other complications.

Patient-Inherent Accidents. Patient-inherent accidents are accidents (other than falls) in which the patient is the primary reason for the accident. Examples are self-inflicted

Symbol	Name	Description
	Flammable and combustible material	Product may catch fire when exposed to heat, sparks, or flame.
	Oxidizing material	Product may cause a fire or explosion if exposed to combustible material.
	Compressed gas	Product is under high pressure. May explode or burst when heated, dropped, or damaged.
	Corrosive material	Product can cause burns to eyes, skin, or respiratory system.
	Dangerously reactive material	Product may react with light, heat, extreme temperatures, or vibration causing explosion, fire, or release of poisonous gases.
	Poisonous and infectious material: immediate and serious toxic effects	Product may be fatal or cause serious or permanent damage if exposed to even once.
	Poisonous and infectious material: other toxic effects	Product may cause cancer, birth defects, or other permanent damage if exposed to repeatedly.
	Poisonous and infectious material: biohazardous and infectious material	Product may cause disease, serious illness, or death.

Figure 36-2 Workplace Hazardous Materials Information System hazard symbols. **Source:** Adapted from the Canadian Centre for Occupational Health and Safety. (2009). *WHMIS labelling requirements*. Retrieved from http://www.ccohs.ca/oshanswers/legisl/msds_lab.html#.

cuts, injuries, and burns; the ingestion or injection of foreign substances; self-mutilation or fire setting; and pinching fingers in drawers or doors. A patient-inherent accident may occur as a result of a **seizure**, a sudden and abnormal discharge of neurons in the brain leading to alterations in sensation, behaviour, movement, perception, or consciousness (Black & Hawks, 2009). Accidental injuries may occur during a seizure if patients hit themselves against an object such as a bed rail or the floor.

Procedure-Related Accidents. Procedure-related accidents are those that occur during therapy. They include medication and fluid administration errors, the improper application of external devices, and accidents related to the improper performance of procedures (e.g., incorrect Foley catheter insertion).

In a study of Canadian hospitals, Baker et al. (2004) found that 7.5% of patients were affected by medical errors during their hospital stay. The most common errors were related to surgical procedures and drug or fluid administration. In 15.9% of these cases, the errors resulted in the death of a patient. Etchells et al. (2008) stress that although medication errors cannot be avoided completely, systems can be designed to minimize the possibility and severity of errors. Providing safe care is an important concern for Canadian nurses (Canadian Nurses Association & University of Toronto Faculty of Nursing,

2004). Nurses and health care facilities must build safety into processes of care and take a systems approach when making efforts to reduce medical errors.

You can prevent many procedure-related accidents (Box 36-2). For example, strictly following the procedure for administering medications prevents medication errors (see Chapter 33). The potential for infection is reduced when surgical asepsis is used for sterile dressing changes or any invasive procedure, such as insertion of a Foley catheter. Finally, the correct use of lifting devices reduces the risk of injuries to yourself and to your patient during transferring and lifting (see Chapter 45). Before moving a patient, begin with an assessment of the patient's capabilities, in particular their ability to weight bear (Canadian Centre for Occupational Health and Safety, 2002). A patient who can bear weight on at least one leg may be transferred with assistance, but you should always use a mechanical lift with a patient who cannot weight-bear. You also need to consider your weight and size relative to the patient's when making decisions about moving patients.

safety alert Always follow agency policy when using lifting devices, and do not use them by yourself. Student nurses should always work with qualified personnel when using these devices.

► BOX 36-2

Nine Life-Saving Patient Safety Solutions

- *Be aware of look-alike and sound-alike medication names.* Carefully review the medication orders of these drugs and use the six rights of medication safety.
- *Use patient identification.* Use two forms of patient identification, such as a hospital arm band and medical record number.
- *Communicate during patient handover.* Communicate critical information, provide time for health care personnel to ask and resolve questions, and involve the patient and family during a handover process.
- *Perform correct procedure at correct body site.* Mark the operative site and take a "time out" to verify that you have identified the correct patient, operative site, and procedure before initiating the procedure.
- *Control concentrated electrolyte solutions.* Use the six rights of medication administration, and follow your agency's protocols for these solutions.
- *Ensure medication accuracy at transitions in care.* Perform medication reconciliation at each health care transition. During admission, transfer, and discharge, compare all medications a patient is taking against the medical order and against the patient's "home medication list."
- *Avoid catheter and tubing misconnections.* Be meticulous in your verification of the catheter and tubing connections, of the correct catheter, and of the correct connection tubing. Label tubing and connections when a patient has multiple catheters.
- *Do not reuse single-use injection devices.* Never reuse needles, injection devices, or intravenous catheters.
- *Improve hand hygiene to prevent health care-associated infections.* Perform hand hygiene before and after each patient encounter and after contact with contaminated objects (even when gloves are worn). Encourage family and visitors to perform hand hygiene before and after visits.

Equipment-Related Accidents. Equipment-related accidents result from the malfunction, disrepair, or misuse of equipment or from an electrical hazard. For example, a too-rapid infusion of intravenous (IV) fluids may result from a dysfunctional IV pump. To avoid accidents, do not operate monitoring or therapy equipment without instruction. A checklist should be used to assess potential electrical hazards to reduce the risk of electrical fires, electrocution, or injury from faulty equipment. In health care settings, clinical engineering staff makes regular safety checks of equipment.

Critical Thinking

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking qualities, and intellectual and professional standards. Clinical judgements require you to anticipate necessary information, analyze the data, and make decisions regarding patient care. Critical thinking is an ongoing process. During assessment (Figure 36-3), you need to consider all critical thinking

Figure 36-3 Critical thinking model for safety assessment.

elements as well as information about the specific patient to make appropriate nursing diagnoses.

In the case of safety, you integrate knowledge from nursing and other scientific disciplines, previous experiences in caring for patients who had an injury or were at risk, critical thinking qualities such as perseverance, and any standards of practice that are applicable. Agency guidelines and professional nursing associations provide standards for nursing activities such as medication administration, fall-prevention steps, and infection control to guide nurses in the provision of safe care. For example, the Registered Nurses' Association of Ontario (2005) has published *Prevention of Falls and Fall Injuries in the Older Adult*. You refer to all this information and experience as you conduct a detailed assessment of a specific patient. For example, while assessing a patient's home environment, you consider typical locations within the home where dangers commonly exist. If a patient has a visual impairment, you apply previous experience in caring for patients with visual changes to anticipate how to thoroughly assess the patient's needs. Critical thinking directs you to anticipate what needs to be assessed and how to make conclusions about available data.

Safety and the Nursing Process

❖ Assessment

To conduct a thorough patient assessment, consider possible threats to a patient's safety, including the patient's immediate environment, as well as any individual risk factors.

Health History

By conducting a health history, you gather data about the patient's level of wellness to determine if any underlying conditions exist that pose threats to safety. For example, you give special attention to assessing the patient's gait, muscle strength and coordination, balance, and vision. A review of the patient's developmental status must be considered as assessment information is analyzed. Also review whether the patient has been exposed to any environmental hazards or is taking medications or undergoing procedures that pose risks. For example,

the use of diuretics increases the frequency of voiding and may result in the patient having to use toilet facilities more often. Falls often occur when patients get out of bed quickly because of urinary urgency.

Patient's Home Environment

When caring for a patient in the home, a home hazard assessment is necessary (Box 36-3). Walk through the home with the patient and discuss how the patient normally conducts daily activities. Key areas to inspect are the bathroom, kitchen, and areas with stairs. For example, when assessing the adequacy of the lighting, you inspect areas where the patient moves and works, such as outside walkways, steps, interior halls, and doorways. Getting a sense of the patient's routine helps you recognize less obvious hazards.

Assessment for the risk of food infection or poisoning involves obtaining a detailed dietary assessment for the previous week; conducting an examination of GI and central

► BOX 36-3 Home Hazard Assessment

Home Exterior

- Are sidewalks uneven?
- Are steps in good repair?
- Is ice and snow removal adequate?
- Do steps and balconies have securely fastened railings?
- Is lighting present and adequate?
- Is outdoor furniture sturdy?
- Are window screens in high-rise apartments properly secured?

Home Interior

- Do all rooms, stairways, and halls have adequate, nonglare lighting?
- Are night lights available?
- Are area rugs secured?
- Are wooden floors nonslippery?
- Are floors where water accumulates covered by nonslip floor mats?
- Is furniture placed appropriately to permit mobility? Is furniture sturdy enough to provide support for getting up and down?
- Are temperature and humidity within normal ranges? Are any steps or thresholds present that may pose a hazard? Are step edges clearly marked with coloured tape? Are handrails available and secure?
- In homes with young children, are window guards and electrical outlet covers installed?
- Can all doors and windows with security gates and locks be opened from the inside without a key?

Kitchen

- Are handwashing facilities available?
- Is the pilot light on for the gas stove?
- Are the stovetop and oven clean?
- Are the dials on the stove readable?
- Are storage areas within easy reach?
- Are fluids such as cleaners and bleach in original containers and stored properly?
- In homes with young children, are safety locks on cabinets and corner counter protectors installed?
- Is the water temperature within a normal range?
- Do clean areas for food storage and preparation exist? Is refrigeration adequate? Are the refrigerator and freezer temperatures correct?

Bathroom

- Are handwashing facilities available?
- Does the tub or shower have skid-proof strips or surfaces? Are bath mats secured?
- Does the patient need grab bars near the bathtub and toilet? Does the patient need an elevated toilet seat?
- Is the medicine cabinet well lit?
- Are medications in their original containers?
- If children live in the home or visit, are medication containers child resistant?
- Have outdated medications been discarded?

Bedroom

- Are beds of adequate height for getting on and off easily?
- Is lighting adequate for both day and night?
- Are floor coverings nonskid?
- Does the patient have a telephone nearby?
- Are emergency numbers visible near the telephone?

Electrical and Fire Hazards

- Are smoke and carbon monoxide detectors installed? Are the batteries for all detectors tested every month and changed twice a year?
- Have the furnace, chimney, and stove been checked for proper ventilation?
- Are extension cords in good condition and used appropriately?
- Are appliances in good working order?
- Are electrical appliances located away from water sources? Is a multipurpose fire extinguisher near the cooking area, and does patient understand how to use it?
- Are combustible items such as oil-based paints, gasoline, and oily rags stored in a garage or basement?
- Are electrical outlets overloaded?
- Are flashlights available?
- Is a first aid kit available to the adult members of the household?
- Does everyone in the family know the fire escape plan and have easy access to emergency phone numbers?

► TABLE 36-1 Hendrich II Fall Risk Model™

Risk Factor	Risk Point	Score
Confusion/Disorientation/Impulsivity	4	
Symptomatic Depression	2	
Altered Elimination	1	
Dizziness/Vertigo	1	
Gender (Male)	1	
Any Administered Antiepileptics (Anticonvulsants): carbamazepine, divalproex sodium, ethosoin, ethosuximide, felbamate, fosphenytoin, gabapentin, lamotrigine, mephenytoin, methsuximide, phenobarbital, phenytoin, primidone, topiramate, trimethadione, valproic acid ¹	2	
Any Administered Benzodiazepines: ² alprazolam, chloridiazepoxide, clonazepam, clorazepate dipotassium, diazepam, flurazepam, halazepam, ³ lorazepam, midazolam, oxazepam, temazepam, triazolam	1	
Get-Up-and-Go Test: "Rising from a Chair"		
If unable to assess, monitor for change in activity level, assess other risk factors, document both on patient chart with date and time.		
Ability to rise in a single movement—No loss of balance with steps	0	
Pushes up, successful in one attempt	1	
Multiple attempts but successful	3	
Unable to rise without assistance during test	4	
If unable to assess, document this on the patient chart with the date and time		
(A score of 5 or greater = High Risk)		
	TOTAL SCORE	

Ongoing medication review updates:

1. Levetiracetam (Keppra) was not assessed during the original research conducted to create the Hendrich Fall Risk Model. As an antiepileptic, levetiracetam does have side effects of somnolence and dizziness, which contribute to its fall risk and should be scored (effective June 2010).

2. The study did not include the effect of benzodiazepine-like drugs since they were not on the market at that time. However, due to their similarity in drug structure, mechanism of action, and drug effects, they should also be scored (effective June 2010).

3. Halazepam was included in the study but is no longer available in the United States (effective June 2010).

Source: Copyright © 2012 by AHI of Indiana, Inc. All rights reserved. U.S. Patent No. 7,282,031 and U.S. Patent No. 7,682,308. Reproduction of copyright and patented materials without authorization is a violation of federal law.

nervous system functions; observing for a fever; and analyzing the results of cultures of feces and vomitus. Suspected food and water sources are also studied. In addition, you should assess the patient's handwashing practices. It is useful to ask patients when they routinely wash their hands, as this can prompt a discussion about the purpose and importance of handwashing.

An assessment of the environmental comfort of the patient's home should include a review of when the patient normally has heating and cooling systems serviced. Does the patient have a functional furnace or space heater? Does the home have air conditioning or fans? Patients who use space heaters must be informed of the risk for fires.

When patients live in older homes, encourage an inspection for the presence of lead in paint, dust, or soil. Because lead can also come from the solder of plumbing fixtures in a home, water from each faucet should also be tested. Local health offices can assist a homeowner in locating a trained lead inspector who will take samples from various locations and have them analyzed at a laboratory for lead content.

Health Care Environment

When a patient is cared for within a health care facility, you must determine if any hazards exist in the immediate care environment. Does the placement of equipment or furniture pose barriers to ambulation? Does the positioning of the patient's bed allow the patient to reach items on a bedside table? Does the patient need assistance with ambulation? Is the patient aware of activity restrictions? Has the patient been taught to use the call bell, and is it within reach? Collaborate with clinical engineering staff to make sure that

equipment has been assessed to ensure its proper function and condition.

Risk for Falls

Assessment of the patient's fall risk factors is essential in determining specific needs and targeting interventions to prevent falls. A fall assessment tool (Table 36-1) can help you determine potential risks before accidents and injuries result. The tool shown in Table 36-1 is the Hendrich II Fall Risk Model. This tool, which is intended for use in acute care settings, takes into account the patient's ability to move independently, as well as other factors that can increase the risk for falls, such as certain types of medications (Gray-Miceli, 2007). Familiarize yourself with the fall assessment tool used in your clinical area as such tools vary among agencies. Patients should be assessed for their risk of falls on admission to the health care setting; an assessment should also be completed after a fall, to determine why the fall occurred, as patients who have fallen are at much greater risk of falling again (Gray-Miceli, 2007; Registered Nurses' Association of Ontario, 2005). In many cases, family members can be significant resources in assessing a patient's fall risk. Families often are able to report on the patient's level of confusion and ability to ambulate.

Risk for Medical Errors

Be alert to factors within your environment that create conditions in which medical errors are more likely to occur. Studies indicate that overwork and fatigue cause a significant decrease in alertness and concentration, leading to errors (Trinkoff et al., 2006). You need to be aware of these factors and include checks and balances when working under stressful conditions. For

example, checking the patient's identification bracelet before beginning any procedure or administering any medication can reduce the risk for error.

The National Steering Committee on Patient Safety (2002) made recommendations to improve the safety of Canada's health care system. At the core of these recommendations was the need to nurture a culture of safety within the system. The Canadian Patient Safety Institute (CPSI) was established in 2003 to provide leadership in the development of such a culture.

Patient Expectations

Patients generally expect to be safe in their home and in the health care setting. However, a patient's viewpoint of what is safe may differ from your viewpoint. For this reason, any assessment must include the patient's understanding of his or her perception of risk factors. This information will be important later if you need to make changes in the patient's environment. Patients usually do not purposefully put themselves in jeopardy. When patients are uninformed or inexperienced, threats to their safety can occur. Patients must always be consulted on ways to reduce hazards in their environment.

❖ Nursing Diagnosis

After completing an assessment of a patient's safety status, review any clusters of data to identify patterns suggesting that safety is threatened. Defining characteristics and related factors from the data guide you in identifying appropriate nursing diagnoses (Box 36-4).

The related factors become the basis for selecting nursing therapies. For example, *risk for injury related to impaired mobility* and *risk for injury related to barriers in the home environment* require different nursing interventions. The patient with altered mobility may require ambulatory aids and physiotherapy. When the related factor is barriers in the home, you recommend changes that will create a safer environment. At

times, as in the example in Box 36-4, multiple related factors may apply. Examples of nursing diagnoses that may apply for patients whose safety is threatened are the following:

- *Impaired home maintenance—risk for imbalanced body temperature*
- *Impaired home maintenance—risk for injury*
- *Deficient knowledge—risk for poisoning*
- *Disturbed sensory perception—risk for suffocation*
- *Disturbed thought processes—risk for trauma*

❖ Planning

During planning, you critically synthesize information from multiple sources (Figure 36-4). Critical thinking ensures that the patient's plan of care integrates all that you have learned about the patient, as well as the key critical thinking elements. For example, reflect on knowledge regarding the services that other disciplines (e.g., occupational therapy) can provide in helping the patient return home safely, as well as on any previous experience wherein a patient benefited from safety interventions. Such experience helps you adapt approaches with a new patient. Applying critical thinking qualities such as creativity helps you and the patient collaborate in planning interventions that are relevant and most useful, particularly when changes are made in the home environment.

► BOX 36-4 NURSING DIAGNOSTIC PROCESS

Assessment Activities	Defining Characteristics	Nursing Diagnosis
Observe patient's mobility and body alignment.	Uncoordinated gait Poor posture	<i>Risk for injury related to impaired mobility, decreased vision, poorly lit home, and cluttered environment</i>
Ask patient about visual acuity.	Reports difficulty seeing at night Reports tripping over rugs and furniture	
Complete a home hazard appraisal.	Poorly lit home Rooms filled with small items Excessive amount of furniture for size of room Rugs not secure	

Figure 36-4 Critical thinking model for safety planning. IV, intravenous.

Goals and Outcomes

Planning and goal setting need to be done in collaboration with the patient, family, and other members of the health care team (Box 36-5). The patient who is an active participant in reducing threats to safety will be more alert to potential hazards. Goals and outcomes must be measurable and realistic, with consideration of the resources available to the patient. The overall goal for a patient with a threat to safety is to remain free from injury. The following are examples of expected outcomes that focus on a patient's need for safety:

- Modifiable hazards will be reduced in the home environment by 100% within one month.
- The patient will not suffer a fall or injury.
- The patient will identify risks associated with visual impairment.

Setting Priorities

Nursing interventions are prioritized to provide safe and efficient care. For example, the patient described in the concept

map (Figure 36-5) has several nursing diagnoses. The patient's mobility problem is an obvious priority because of its influence on skin integrity and the risk for falls. Plan individualized interventions based on the severity of risk factors and the patient's developmental stage, level of health, lifestyle, and culture (Box 36-6). Planning also involves understanding the patient's need to maintain independence within physical and cognitive capabilities. You and the patient collaborate to establish ways of maintaining the patient's active involvement within the home and health care environment. Educating the patient and family is also an important intervention to reduce safety risks over the long term.

Continuity of Care

Patients need to learn how to identify and select resources within their community that enhance safety (e.g., block parent homes, local police departments, and neighbours willing to check on a patient's well-being). Collaboration with the patient and family and other disciplines such as social work and

► BOX 36-5 NURSING CARE PLAN

Risk for Injury

Assessment

Mr. Key, a visiting nurse, is seeing Ms. Cohen, an 85-year-old woman, at her home. The patient has been recovering from a mild stroke affecting her left side. Ms. Cohen lives alone but receives regular assistance from her daughter and son, who both live within 16 km. Mr. Key's assessment includes a discussion of Ms. Cohen's health problem and how the stroke has affected her, as well as a pertinent physical examination.

Assessment Activities

Findings and Defining Characteristics

Ask Ms. Cohen how the stroke has affected her mobility.

She responds, "I bump into things, and I'm afraid I'm going to fall."

Conduct a home hazard assessment.

Cabinets in the kitchen are in disarray and full of breakable items that could fall out. Throw rugs are on floors; bathroom lighting is poor (40-W bulb); bathtub lacks safety strips and grab bars; and home is cluttered with furniture and small objects.

Observe Ms. Cohen's gait and posture.

Ms. Cohen has kyphosis and has a hesitant, uncoordinated gait. She frequently holds walls for support.

Assess Ms. Cohen's muscle strength.

The left arm and leg are weaker than the right.

Assess visual acuity with corrective lenses.

Ms. Cohen has trouble reading and seeing familiar objects at a distance while wearing current glasses.

Nursing Diagnosis: Risk for injury related to impaired mobility, decreased visual acuity, and physical environmental hazards.

Planning

Goals (Nursing Outcomes Classification)*

Expected Outcomes

Home will be free of hazards within 1 month.

Risk Control

Modifiable hazards in kitchen and hallway will be reduced in the home within 1 week. Revisions to bathroom will be completed in 1 month.

Patient and family will be knowledgeable of potential hazards for patient's age group within 1 week.

Knowledge: Personal Safety

Patient and her daughter will identify risks and the steps to avoid them in the home at the conclusion of a teaching session next week.

Patient will express greater sense of feeling safe from falls in 1 month.

Fall Prevention Behaviour

Patient will report improved vision with the aid of new eyeglasses.

Patient will be free of injury within 2 weeks.

Patient will be able to safely ambulate throughout the home and perform personal care activities within 2 weeks.

*Outcome classification labels from Moorhead, S., Johnson, M., Maas, M. L., & Swanson, E. (Eds.). (2008). *Nursing outcomes classification (NIC)* (4th ed.). St Louis, MO: Mosby.

BOX 36-5 NURSING CARE PLAN—cont'd

Interventions (Nursing Interventions Classification)[†]

Fall Prevention

Review findings from home hazard assessment with patient and her daughter.

Establish a list of priorities to modify. Have patient's son assist in installing bathroom safety devices.

Install lighting (75-W bulbs, nonglare) throughout the home. Have patient's son install blinds over kitchen windows.

Discuss with patient and daughter the normal changes of aging, effects of recent stroke, associated risks for injury, and how to reduce risks.

Encourage daughter to schedule patient's vision testing for new prescription within 2–4 weeks.

Refer patient to a physiotherapist to assess need for assistive devices for kyphosis, left-sided weakness, and gait.

Rationale

Fall risks for homebound older adults include visual disturbances, unsteady gait, and postural changes (Meiner & Lueckenotte, 2006). Evaluation of home hazards will highlight extrinsic factors that may lead to falls.

Modification of environment reduces fall risk (McCullagh, 2006).

With aging, the pupil loses the ability to adjust to light, causing sensitivity to glare. Glare can make it difficult to clearly see a walking path (Meiner & Lueckenotte, 2006).

Education regarding management of hazards can reduce fear of falling (Ebersole et al., 2008).

Improved visual acuity reduces incidence of falls (Edelman & Mandle, 2006).

Exercise often improves gait, balance, and flexibility. Modifying gait problems by increasing lower extremity strength reduces fall risk.

[†]Intervention classification labels from Bulechek, G. M., Butcher, H. K., & Dochterman, J. M. (Eds.). (2008). *Nursing interventions classification (NIC)* (5th ed.). St. Louis, MO: Mosby.

Evaluation

Nursing Actions

Patient Response and Finding

Achievement of Outcome

Ask patient and family to identify risks.

Ms. Cohen and her daughter are able to identify risks during a walk through the home and expressed a greater sense of safety as a result of changes made.

Ms. Cohen and her daughter are more knowledgeable of potential hazards.

Observe environment for elimination of hazards.

Throw rugs have been removed. Lighting has been increased to 75 W, except in the bathroom and bedroom.

Environmental hazards have been partially reduced.

Reassess Ms. Cohen's visual acuity.

Ms. Cohen has new glasses and says she can read better and see distant objects more clearly.

Ms. Cohen's vision has improved, enabling her to ambulate more safely.

Observe Ms. Cohen's gait and posture.

Ms. Cohen's gait remains hesitant and uncoordinated; she reports that her daughter has not had time to take her to the physiotherapist.

The outcome of safe ambulation has not been totally achieved; continue to encourage Ms. Cohen and daughter to go to physiotherapy appointment.

occupational and physiotherapy may become an important part of your plan of care. For example, a hospitalized patient may need to go to a rehabilitation facility to gain strength and endurance before being discharged home. Be sure that the patient and family understand the need for resources and are willing to make changes that will promote the patient's safety.

❖ Implementation

Nursing interventions are directed toward ensuring a patient's safety in all settings and include health promotion, developmental interventions, environmental interventions, and limiting specific risks to patient safety.

Health Promotion

To promote a patient's health, it is necessary for the individual to be in a safe environment and to practise a lifestyle that minimizes the risk of injury. Edelman and Mandle (2006) described passive and active strategies aimed at health promotion. Passive strategies are implemented through public health

and government legislative interventions (e.g., sanitation and clean water laws). Active strategies are those in which the individual is actively involved through changes in lifestyle (e.g., wearing a seat belt or installing outdoor lighting) and participation in wellness programs.

You can participate by supporting legislation and working in community-based settings. Because environmental and community values have the greatest influence on health promotion, community and home health nurses assess and recommend safety measures in the home (see Box 36-3), school, neighbourhood, and workplace.

Developmental Interventions

Accidents involving children are mostly preventable, and parents need to be aware of specific dangers at each stage of growth and development. Accident prevention thus requires health education for parents and the removal of dangers whenever possible. You are frequently in a position to educate parents about reducing the risks of injuries for young children (see Chapter 22). Nurses working in prenatal and postpartum

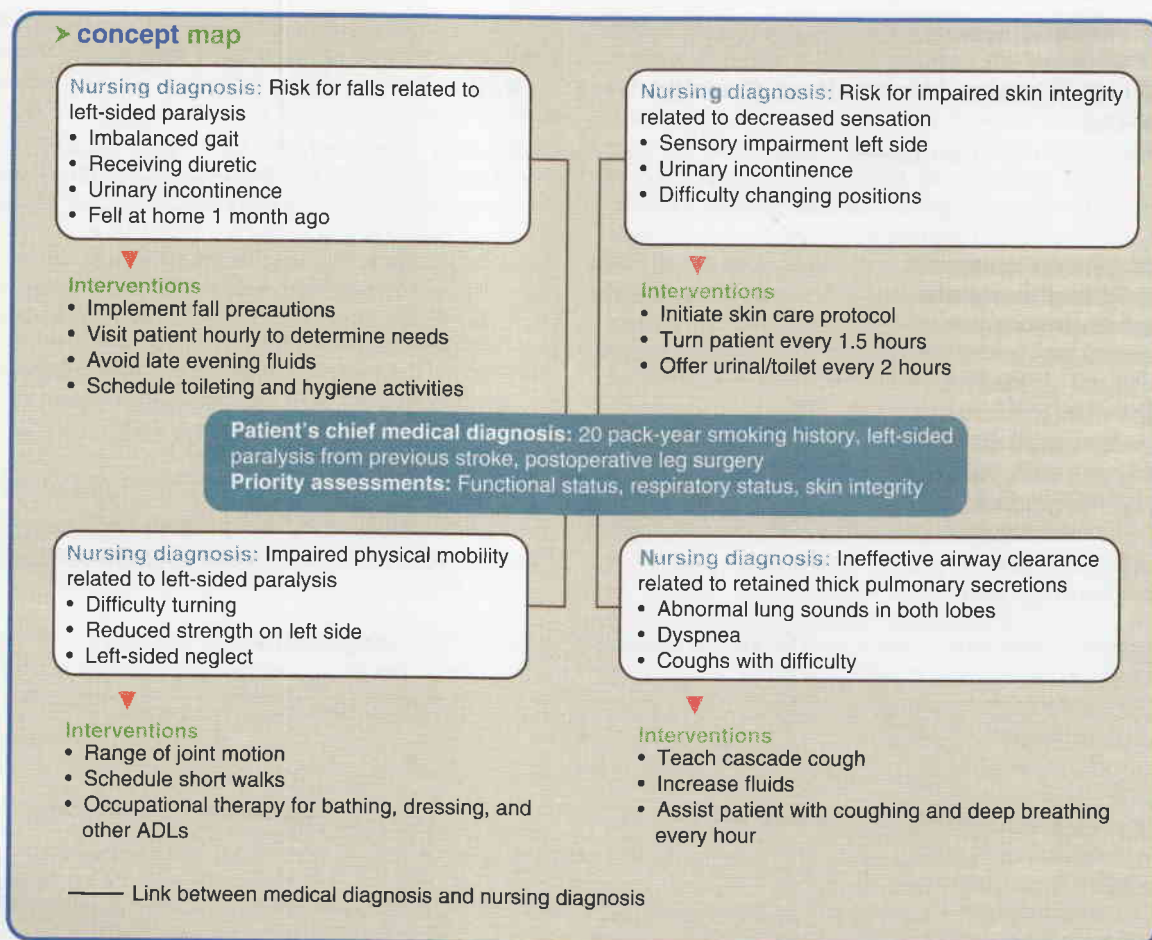

Figure 36-5 Concept map for a patient with a cerebrovascular accident three months previously with left-sided paralysis, two days after right femoral–popliteal bypass. ADLs, Activities of daily living.

* BOX 36-6 CULTURAL ASPECTS OF CARE

Cultural phenomena affecting health and safety include attitudes toward personal space, social organizations, communication, and environmental control. While conducting a home assessment for risks to safety, remember that you have entered the patient's territory and that the patient's attitude toward his or her residence and belongings must be appreciated. For example, patients from Western Europe and the British Isles may be considered aloof and distant with regard to personal space. It may be very difficult for them to have an outsider in their home who suggests changes regarding their personal belongings to reduce physical hazards. It is particularly difficult to determine a patient's attitude toward his or her home environment when the patient's primary language and that of the health care provider differ.

Another culturally sensitive issue involves the patient's sense of environmental control. Be aware of health beliefs and practices that will affect the outcome of interventions. For example, a reliance on family and religious organizations, as opposed to community resources, may affect the patient's compliance with nursing interventions and referrals.

Learn to ask questions sensitively and to show respect for different cultural beliefs. Adapting to different cultural beliefs and practices requires flexibility. Respect for the belief systems of others and the effects of those beliefs on the patient's well-being are critically important to competent health care. You must have the ability and knowledge to communicate about and to understand health behaviors influenced by culture.

Implications for Practice

- Resistance to change long-standing habits can interfere with a cultural group's acceptance of injury-prevention practices. Include family members who have a strong influence, such as a dominant man or older woman, when providing safety education.
- Evaluate the use of traditional ethnic remedies or foods that contain lead; these can increase a patient's risk for lead poisoning.
- Remember that living in rural areas and in manufactured housing places the patient at greater risk for fire-related injuries and death.
- Stress the importance of having fully functioning smoke detectors and a multipurpose fire extinguisher.
- Assess the patient's smoking and drinking habits. Residential fire deaths are often attributed to the use of cigarettes and alcohol.
- Patients who live in poverty and have low educational levels are at greater risk for injury and disease. Assist the patient and family in identifying community resources, such as the local health office or clinic.
- Be aware of family patterns and how the patient and family interact with each other. Family disruption and weak intergenerational ties can increase a patient's risk for injury from violent behaviour.

settings can incorporate safety into the care plan of the child-bearing family. Community health nurses can assess the home and show parents how to promote safety in their homes (see Table 36-2 and Figures 36-6 and 36-7). The following discussion highlights some specific risks at different developmental stages.

Infants, Toddlers, and Preschoolers. Small children must be protected from accidental poisoning. Strategies for prevention of the accidental ingestion of poisonous materials are outlined in Table 36-2. In any instance of accidental poisoning, guidelines for intervening (Box 36-7) should be adhered to. The poison control centre phone number should be visible

Figure 36-6 Safety covers for electrical outlets.

► TABLE 36-2 Interventions to Promote Safety for Children and Adolescents

Intervention

Infants and Toddlers

- Ensure that infants sleep on their backs. Teach parents the mnemonic “back to sleep.”
- Ensure that parents do not fill cribs with pillows, large stuffed toys, or comforters. Sheets should fit snugly.
- Ensure that pacifiers are not attached to a string or ribbon and placed around a child’s neck.
- Ensure that all instructions for preparing and storing formula are being followed.
- Ensure that only large, soft toys without small parts such as buttons are being used.
- Teach parents that playpens with mesh sides should not be left with a side down; spaces between crib slats should be <6 cm apart.
- Teach parents to never leave crib sides down or leave babies unattended on change tables or in infant seats, swings, strollers, or high chairs.
- Teach parents to discontinue using accessories such as infant seats and swings when the child becomes too active or physically too big.
- Teach parents to never leave a child alone in the bathroom, in the tub, or near any water source (e.g., a pool).
- Teach parents strategies to baby-proof the home:
 - Install safety locks on floor-level cabinets
 - Use child-resistant caps
 - Place small or sharp objects, medications, and cleaning agents out of children’s reach
 - Leave potentially poisonous materials in their original containers
 - Remove poisonous plants from the home
- Also ensure that parents are aware that poisoning can result from swallowing miniature button or disc batteries, commonly found in games, cameras, calculators, and watches.
- Teach parents to remove plastic bags from the cleaners or grocery store from the home.
- Ensure that electrical outlets are protected by covers (Figure 37-6).
- Ensure that window guards are on all windows.
- Ensure that keyless locks (e.g., deadbolts) have been installed on doors above a child’s reach (even when they are standing on a chair).

Rationale

- Sleeping on the back is associated with the lowest risk of sudden infant death syndrome (SIDS) (Canadian Pediatric Society, 2010a).
- Infants may become entwined in sheets and other bedding and suffocate (Canadian Pediatric Society, 2010a).
- Choking may occur.
- Proper formula preparation and storage prevents contamination.
 - A formula may come in a concentrated form, or it may already be diluted and ready to use. Following directions ensures the proper concentration of the formula. Undiluted formula can cause fluid and electrolyte disturbances; overly diluted formula does not provide sufficient nutrients.
- Small parts can become dislodged, and choking and aspiration are possible.
- A child’s head may become wedged in the lowered mesh side or between crib slats, and asphyxiation may occur.
- Infants and toddlers can roll or move and fall from change tables or out of accessories such as infant seats or swings.
- When physically active or too big, the child can fall out of or tip over these accessories and suffer an injury.
- Accidental drowning may occur.
- Babies explore their world with their hands and mouth.
 - Choking and poisoning may occur.
- Suffocation may occur if plastic covers the nose and mouth.
- Crawling babies may insert objects into outlets and experience an electrical shock.
- Guards prevent children from falling out of windows.
- Keyless locks prevent a toddler from leaving the house and wandering off. Death from exposure, car accidents, and drowning may occur if a toddler wanders away. Keyless locks allow for rapid exit in the case of fire.

Continued

► **TABLE 36-2 Interventions to Promote Safety for Children and Adolescents—cont'd**

Intervention	Rationale
Teach parents that children weighing <36 kg must always be in an age- and weight-appropriate car seat that has been installed according to the manufacturer's instructions (Figure 37-7). This includes car seats and booster seats. Children under 13 years should be in the back seat of the car. All passengers should wear their seat belts (Canadian Pediatric Society, 2011). Encourage caregivers to learn cardiopulmonary resuscitation and the Heimlich manoeuvre.	In case of a sudden stop or crash, an unrestrained child may suffer severe head injuries and death. Caregivers should be prepared to intervene in acute emergencies, such as choking.
Preschoolers	
Encourage parents to teach children to swim at an early age, but always provide supervision near water. Encourage parents to teach children how to cross streets and walk in parking lots. Instruct them to never run out into the street after a ball or toy. Encourage parents to teach children not to talk to, go with, or accept any item from a stranger. Children should also be taught not to go with a known adult unless they have their parent's permission (Child Find Canada, 2006). Encourage parents to teach children basic physical safety rules, such as the proper use of safety scissors, never running with an object in their mouth or hand, and never attempting to use the stove or oven unassisted. Encourage parents to teach children not to eat items found in the street or grass. Teach parents to remove doors from unused refrigerators and freezers and to instruct children not to play or hide in a car trunk or unused appliances.	Swimming is a useful skill that may someday save a child's life. However, all children need constant supervision near water. Pedestrian accidents involving young children are common. This precaution reduces the risk of exploitation and abduction. The risk of injury is lower if children are taught basic safety procedures. Poisoning may occur. If a child cannot freely exit from an appliance or car trunks, asphyxiation may occur.
School-Aged Children	
Encourage parents to teach children the safe use of equipment for play and work. Encourage parents to teach children proper bicycle safety, including the use of a helmet and rules of the road. Encourage parents to teach children proper techniques for specific sports, as well as the need to wear proper safety gear (e.g., eyewear or mouth guards). Encourage parents to teach children not to operate electrical equipment while unsupervised. Teach parents that children should never have access to firearms or other weapons. All firearms should be kept in locked cabinets. Encourage parents to teach children safe use of the Internet.	Children need to learn the safe, appropriate use of implements to avoid injury. These safety precautions may reduce injuries from falling off a bike or being hit by a car. The use of proper sports techniques, the correct equipment, and protective gear prevents injuries. If an electrical mishap were to occur, no one would be available to help. Children are often fascinated by firearms and weapons and may attempt to play with them. Children are vulnerable to being exploited by predators over the Internet.
Adolescents	
Encourage enrollment in driver's education classes. Provide information about the effects of using alcohol, drugs, or other substances (e.g., glue, aerosols, or gasoline). Provide sex education, including safer sex practices, birth control, and abstinence. Refer adolescents to community and school-sponsored activities. Encourage mentoring relationships between adults and adolescents. Teach adolescents the safe use of the Internet.	Many injuries in this age group are related to motor vehicle accidents. Adolescents are prone to risk-taking behaviours and are subject to peer pressure. Many adolescents begin sexual relationships. Pregnancy and sexually transmitted infections may result. Adolescents need to socialize with peers yet need some supervision. Adolescents are in need of role models after whom they can pattern their behaviour. Safe use of the Internet avoids overuse and possible exposure to inappropriate Web sites.

Adapted from Hockenberry, M., & Wilson, D. (2007). *Wong's nursing care of infants and children* (8th ed.). St Louis, MO: Mosby.

► BOX 36-7 Procedural Guideline

Interventions for Accidental Poisoning

Teach parents to call 911 or emergency services immediately if their child is unconscious, not breathing, or having convulsions or seizures due to poison contact or ingestion. If they think that their child has come in contact with poison and has mild or no symptoms, they should call their local poison control centre. Phone numbers for poison control centres across Canada can be accessed at <http://www.aboutkidshealth.ca/En/HealthAZ/TestsAndTreatments/Resources/Pages/Poison-Information-Centres-in-Canada.aspx> (AboutKidsHealth.ca, 2011).

Different types and methods of poisoning require different, immediate treatment:

- Swallowed poison—Remove the item from the child, and have the child spit out any remaining substance. Do not make your child vomit. Do not use syrup of ipecac.
- Skin poison—Remove the child's clothes and rinse the skin with lukewarm water for at least 15 minutes.
- Eye poison—Flush the child's eye by holding the eyelid open and pouring a steady stream of room-temperature water into the inner corner.
- Poisonous fumes—Take the child outside or into fresh air immediately. If the child has stopped breathing, start cardiopulmonary resuscitation (CPR) and do not stop until the child breathes on his or her own, or until someone can take over (American Academy of Pediatrics/Healthy Children.org, 2009).

School-Aged Children. School-aged children increasingly explore their environment (see Chapter 22). They may travel to and from school on foot or by school bus, and they may have friends outside their immediate neighbourhood. They may also become more active in extracurricular activities. Parents, teachers, and nurses must instruct children in safe practices to follow at school and play. Table 36-2 lists nursing interventions to help guide parents in providing for the safety of school-aged children. Using examples when discussing safe practices is an effective way to teach school-aged children.

Because school-aged children participate in more activities outside their home and neighbourhood environments, they are at greater risk of injury from strangers. Children should be warned repeatedly not to accept candy, food, gifts, or rides from strangers, and not to go anywhere with a known adult unless they have their parent's permission. In addition, children need to know what to do if a stranger approaches. Frequently, neighbourhoods have a "block parent" program. The owner of a block parent home ensures that an adult is home during the times when children are walking to and from school. If a stranger approaches a child, the child can run to that home (identified by a sign), and the adult will protect the child and call the proper authorities. You may work with school systems or neighbourhoods to initiate such a system to protect children.

Sports safety is stressed in school sports, but parents and health care providers can reinforce these safety tips by insisting that children wear protective gear while participating in sports such as skateboarding and snowboarding. For example, schools provide hard batting helmets for baseball games, and parents should also provide this equipment when children are playing baseball in their own backyards.

Bicycle- and scooter-related injuries are a major cause of death and disability among children. Bikes should be in good

Figure 36-7 Infant car seat. A, Infant seat with base. B, "3-in-1" convertible seat—infant/child/booster seat. C, Infant/child/booster seat. D, Child/booster seat. E, Backless booster seat. F, High-back booster seat. G, Combination (child/booster) seatbelt-positioning booster seat mode. **Source:** Canadian Pediatric Society. (2011). *Keeping kids safe*. Retrieved from <http://www.caringforkids.cps.ca/keepkidssafe/CarSeatSafety.htm>.

on the telephone in homes with young children, and the centre should be called immediately if poisoning is suspected.

Educate parents that children under five years of age are also more susceptible to infectious diseases. The recommended vaccination schedule begins in infancy and protects children from potentially life-threatening illnesses such as whooping cough, measles, mumps, chickenpox, and meningitis (Canadian Pediatric Society, 2010b).

Figure 36-8 Proper bicycle safety equipment for school-aged children.

working order and the proper size for the child. Children under the age of 10 years should not be permitted to ride their bike on the road, as they have not yet developed the combined physical and cognitive skills to do this safely (Safe Kids Canada, 2010). They should also be cautioned not to engage in dangerous stunts or activities while bike riding. A properly fitted helmet should be worn, as it can decrease the risk of head injury by up to 85% (Safe Kids Canada, 2010). Because most fatalities from bicycle accidents are related to head injuries, most provinces have implemented laws requiring that children wear bicycle helmets while cycling (Figure 36-8).

Adolescents. Risks to the safety of adolescents involve many factors outside the home environment, particularly their almost constant involvement with their peers (see Chapter 22). Adults serve as role models for adolescents and, through providing examples, setting expectations, and providing education, can help adolescents minimize risks to their safety. For example, adolescents who are considering getting a body piercing or tattoo need information about the risks for complications with these procedures and strategies for minimizing these risks. This age group has a high incidence of suicide because of feelings of decreased self-worth and hopelessness. You should be aware of the risks posed at this time and be prepared to teach adolescents and their parents measures to prevent accidents and injury (see Table 36-2).

When adolescents learn to drive, their environment expands and so does their risk for injury. The potential for motor vehicle accidents is higher among teen drivers than in any other age group. Teens are more likely to speed, run red lights, and drive while intoxicated. The young driver must be taught to comply with rules and regulations when using a car.

safety alert Reinforce to new drivers and their parents the need to consistently wear safety belts and to never ride in a car with a driver who may be intoxicated. Assist parents and their teen in developing a plan of action to be used if the teen finds himself or herself with a driver who has been drinking or has used other substances.

Because adolescence is a time when mature sexual physical characteristics develop, adolescents may begin to have physical relationships with others. They need prompt, accurate instruction to prevent pregnancy and the spread of sexually transmitted disease (see Chapter 26).

Adults. Risks to young and middle-aged adults frequently result from lifestyle factors such as postpartum depression, high stress levels, inadequate nutrition, the use of firearms, excessive alcohol intake, and substance abuse (see Chapter 23). In our fast-paced society, there appears to be more expression of anger, which can quickly precipitate accidents (e.g., “road rage”). Adults need to have the opportunity to discuss the choices they have made in their life and the types of threats to safety that exist. Given information about threats to their well-being, adults may make the necessary modifications to their lifestyle practices. Useful resources are stress-management centres, employee-assistance programs, and health-promotion activities, which can be found in many communities and hospitals. In addition, neighbourhood centres, community clinics, and outpatient clinics are equipped to assist adults in modifying lifestyle habits that present risks to their health (e.g., smoking, overeating, lack of exercise, alcoholism).

Older Adults. Nursing interventions for older adults are designed to reduce the risk of falls and other accidents and to compensate for the physiological changes of aging (Box 36-8).

In older adults, diminished eyesight and impaired memory may result in an accidental overdose or missed doses of prescribed medications. The use of medication organizers that are filled once a week by the patient or family can help to prevent such errors. These organizers have the day and time on each box so that the patient knows when and what to take at any given time (Figure 36-9). They can be purchased at any drugstore at a very reasonable cost. Medication not in use or out of date should be taken to a pharmacy or municipal waste disposal depot for proper disposal (Health Canada, 2011).

Burns and scalds are also more apt to occur with older individuals because they may become confused when turning the dials on a stove or other heating appliance. Nursing measures for preventing burns are designed to minimize the risk presented by impaired vision. Hot water faucets and dials can be colour coded to make it easier for the adult to know what has been turned on. Lowering the thermostat setting on the water heater reduces the risk of scalding.

Older adults are more likely to have motor vehicle accidents because of three specific physiological changes. First, changes in visual acuity, depth perception, and peripheral vision prevent these patients from quickly observing situations in which an accident is likely to occur. Second, decreased hearing acuity alters older adults’ ability to hear emergency vehicle sirens or car and truck horns. Third, because of a decreased nervous system response, older adults may be unable to react as quickly as they once could to avoid an accident. A decline in these skills may account for the most common types of accidents, including right-of-way and turning accidents. Educate patients regarding safe driving (e.g., driving shorter distances or only in daylight, using side- and rear-view mirrors carefully, and looking back toward their “blind spot” before changing lanes). If hearing is a problem, patients might try keeping a window rolled down while driving or reducing the volume of the radio or music.

Eventually, counselling may be necessary to help a patient make the decision of when to stop driving. This is not an easy decision as it can have implications for the patient’s self-concept and self-esteem. It also has practical implications—the individual who has been accustomed to driving to daily activities will have to find alternative transportation. As a result, the patient may resist giving up his or her driver’s licence and vehicle. You can support the decision to stop driving by

BOX 36-8 FOCUS ON OLDER ADULTS

- Older adults experience alterations in vision and hearing. Encourage yearly vision and hearing examinations and frequent cleaning of glasses and hearing aids as a means of preventing falls and burns.
- Older adults may have slower reaction times. Teach patients safety tips for avoiding motor vehicle accidents. Driving may need to be restricted to daylight hours or suspended altogether.
- Range of motion, flexibility, and strength are decreased. Encourage supervised exercise classes for older adults and teach them to seek assistance with household tasks as needed. Assess whether safety features, such as grab bars in the bathroom, are needed.
- Reflexes are slowed, and the ability to respond to multiple stimuli is reduced. Provide adequate, meaningful stimuli but prevent sensory overload.
- Nocturia and incontinence are more frequent in older adults. Institute a regular toileting schedule for the patient. A recommended frequency is every three hours. Diuretics are generally given in the morning; however, you should speak with your patient about his or her response to the drug to determine the best timing. Assistance should be provided, along with adequate lighting, to patients who need to use the bathroom at night.
- The family plays a significant role in the care of older adults. Often, family members serve as informal caregivers for older adults. In Canada in 2006, 30% of women and 22% of men between the ages of 45 and 54 provided informal care to an older adult (Vanier Institute of the Family, 2010). Encourage the family to allow the older adult to remain as independent as possible and to provide help for only those things that are necessary.
- The high prevalence of chronic conditions in older adults results in the use of a high number of prescription and over-the-counter medications. Coupled with age-related changes in pharmacokinetics, this presents a greater risk of serious adverse effects. Medications typically prescribed for older adults include anticholinergics, diuretics, anxiolytic and hypnotic agents, antidepressants, antihypertensives, vasodilators, analgesics, and laxatives, all of which may themselves pose risks or interact with other medications to increase the risk for falls. Review the patient's drug profile to ensure that any of the above noted drugs are used cautiously, and assess the patient regularly for any adverse effects that may increase the risk for falls.

offering anticipatory guidance when an illness with progressive impairment is diagnosed, working with family members to determine how to approach the issue with the patient, and providing information about objective assessment of driver ability (DriveABLE, 2010). When your patients make this decision, help them locate resources in the community that provide transportation.

Pedestrian accidents can be reduced by persuading individuals to wear reflectors on garments when walking at night; to stand on the sidewalk and not in the street when waiting to cross; to always cross at corners and not in the middle of the block (particularly on a major street); to cross with the traffic light and not against it; and to look left, right, and left again before entering the street or crosswalk.

Environmental Interventions

You can implement specific interventions aimed at maintaining a safe environment. Particularly important are measures for preventing fires and dealing with them if they do occur. Other environmental interventions are those that address basic needs, physical hazards, and the transmission of pathogens.

Fires. A fire is always possible in the home or health care facility. Accidental home fires typically result from smoking in bed, placing cigarettes in trash cans, cooking accidents, or faulty wiring or appliances. Institutional fires typically result from electrical or anaesthetic-related causes. Although smoking is usually not allowed in the health care setting, smoking-related fires continue to pose a significant risk as a result of unauthorized smoking in bed.

The interventions described here are directed toward fires occurring in health care agencies, but the same principles apply for fires in the home (Box 36-9). Smoke detectors (Figure 36-10) should be placed strategically throughout the home and checked regularly. Multipurpose fire extinguishers should be installed near the kitchen and any workshop areas.

In the home, it is important to have a plan of action in the event of fire, including a route of exit, a location where family members will meet, and the identification of who will help individuals in need of assistance. A fire drill should be held to practise this plan once or twice each year. Although having an escape plan is necessary for all families, it is particularly important for families with disabled individuals. All patients, even young children, should be familiar with the phrase “stop,

BOX 36-9

Fire Intervention Guidelines for Nurses Working in Health Care Agencies

- Ensure that the phone number for reporting fires appears on the telephone and is visible at all times.
- Know your agency's mnemonic (if any), fire drill, and evacuation plan.
- Know the location of all fire alarms, exits, extinguishers, and the oxygen shut-off.
- Use the mnemonic RACE to set priorities in case of fire:
Rescue and remove all patients in immediate danger.
Activate the alarm. Always do this before attempting to extinguish even a minor fire.
Confine the fire by closing doors and windows and turning off oxygen and electrical equipment.
Extinguish the fire using an extinguisher (see Box 36-10).

Figure 36-9 The One-Day-At-A-Time medicine organizer. **Source:** Courtesy Apothecary Products, Inc. Burnsville, MN.

Figure 36-10 Smoke and fire detector.

drop, and roll,” which describes the actions to be followed when a patient’s clothing or skin are burning.

If a fire occurs in a health care agency, you protect patients from immediate injury, report the exact location of the fire, and contain the fire and extinguish it if possible. All personnel are mobilized to evacuate patients. Patients who are close to the fire, regardless of its size, are at risk of injury and should be moved to another area. If a patient is receiving oxygen but not life support, discontinue the oxygen because it supports combustion and can fuel an existing fire. If the patient is on life support, you may need to maintain the patient’s respiratory status manually with an Ambu-bag (see Chapter 38) until the patient is moved away from the fire and the ventilator can be restarted. Ambulatory patients can be directed to walk by themselves to a safe area and, in some cases, may be able to assist in moving patients in wheelchairs. Bedridden patients are generally moved from the scene of a fire on a stretcher, in their bed, or in a wheelchair. If none of these methods is appropriate, patients must be carried from the area. If a patient must be carried, be careful not to overextend your physical limits for lifting because an injury to you can result in further injury to the patient. If fire department personnel are on the scene, they can help evacuate patients.

After a fire has been reported and patients are out of danger, nurses and other personnel must take measures to contain or put out the fire, such as closing doors and windows, placing wet towels along the base of doors, turning off oxygen and electrical equipment, and using a fire extinguisher. Fire extinguishers commonly seen in the clinical setting are categorized as type A, used for ordinary combustibles (e.g., wood, cloth, paper, and many plastic items); type B, used for flammable liquids (e.g., gasoline, grease, paint, and anaesthetic gas); and type C, used for electrical equipment. Extinguishers labelled ABC Multipurpose can be used for any of the above types of fire. The correct use of an extinguisher is discussed in Box 36-10 and demonstrated in Figure 36-11.

The best intervention is to prevent fires. Nursing measures include complying with your agency’s smoking policies and keeping combustible materials away from heat sources. Some agencies have fire doors that are held open by magnets and

BOX 36-10 PATIENT TEACHING

Correct Use of a Fire Extinguisher in the Home

Objectives

- Patient will correctly place the extinguisher in the home.
- Patient will describe when it is appropriate to use a home fire extinguisher.
- Patient will demonstrate the correct technique when using a fire extinguisher.
- Patient will state when fire extinguishers need to be replaced.

Teaching Strategies

- Discuss correct location of the fire extinguisher. It is recommended that one be placed on each level of the home, near an exit, in clear view, away from stoves and heating appliances, and above the reach of small children. Keep a fire extinguisher in the kitchen, laundry room, workshop, and garage. The instructions should be read when the extinguisher is purchased and kept available for periodic review.
- Describe the steps to take before using the extinguisher. The patient should attempt to fight the fire only after all occupants have left the home, the fire department has been called, the fire is confined to a small area, an exit route is readily available, the extinguisher is the right type for the fire (see the text for a description of extinguisher types), and the patient knows how to use the extinguisher.
- Instruct the patient to memorize the mnemonic PASS: **P**ull the pin to unlock handle; **A**im low at the base of the fire; **S**queeze the handle; and **S**weep the unit from side to side (see Figure 36-11).

Evaluation

- Observe the patient correctly installing an extinguisher in the home.
- Ask the patient to correctly list the steps to take before attempting to use an extinguisher.
- Ask the patient to demonstrate the correct use of the extinguisher while reciting the instructions with the mnemonic PASS.

Source: Adapted from Windsor Fire & Rescue Services. (2011). *Home fire extinguisher guidelines*. Windsor, ON: Author. Retrieved from <http://www.windsorfire.com/divisions-prevention-home-fire-extinguisher-guidelines>.

close automatically when a fire alarm sounds. It is important to keep equipment away from these doors.

Other Environmental Interventions. You can contribute to a safer environment by helping your patients meet basic needs related to oxygen, humidity, nutrition, and temperature. To ensure that oxygen availability is not threatened, recommend that patients living at home have annual inspections of the heating system, chimney, and appliances. Carbon monoxide detectors are available for home use at a reasonable cost but should not be considered a replacement for the proper use and maintenance of fuel-burning appliances. To achieve a comfortable level of humidity in the home, patients can attach a humidifier to the furnace or, in the case of patients who have upper respiratory tract infections, use a room humidifier where they sleep. Teach basic techniques for food handling (e.g., handwashing and checking for spoilage) and preparation (e.g., keeping food refrigerated before serving) so that nutritional

Pull the pin. Some models require you to remove a locking pin on the handle or lever. Some models may have other lever-releasing mechanisms, such as a button.

Aim low and direct the hose nozzle or cone at the base of the fire. If you aim at the flames, which most inexperienced users are tempted to do, the extinguishing agent will flow right through the flames, and be ineffective. You want the extinguishing agent to hit the base of the fire. Follow the manufacturer's instructions on the safe distance from which to fight the fire. Most portable fire extinguishers must be used from a distance of 1.8 to 3 metres (6 to 10 feet) to be effective.

Squeeze the lever above the handle to discharge the extinguishing agent. Releasing the lever will stop the discharge. Some models may have a button instead of a lever.

Sweep the nozzle or hose from side to side at the base of the fire. Moving carefully toward the fire, keep the extinguisher aimed at the base of the fire and sweep back and forth until the flames appear to be out. Never turn your back on a fire; watch the fire area in case the fire re-ignites, and repeat use of the extinguisher if necessary.

Figure 36-11 The correct use of a fire extinguisher. **Source:** Windsor Fire.com (2011). *Home fire extinguisher guidelines*. Retrieved from <http://www.windsorfire.com/divisions-prevention-home-fire-extinguisher-guidelines>.

needs are met safely. It is also helpful for family members to date leftovers. Older adults who have difficulty preparing their own food may benefit from Meals on Wheels, an organization that provides fresh, nutritious meals in the home. Patient education for older adults and patients who enjoy outdoor activities should include ways to prevent and treat frostbite, hypothermia, heatstroke, and heat exhaustion (see Chapter 30).

Adequate lighting and security measures in and around the home, including the use of night lights, exterior lighting, and good-quality locks on windows and doors, enable patients to

reduce the risk of injury from crime. Local police departments and community organizations often have safety classes available to teach residents how to take precautions to minimize the chance of becoming involved in a crime. Some useful tips include always parking the car near a bright light or in a busy public area, carrying a whistle attached to the car keys, keeping car doors locked while driving, and always paying attention while driving to notice if anyone starts to follow the car. Patients should be encouraged to join block associations and work closely with law enforcement personnel to reduce crime in their neighbourhoods.

To prevent the transmission of pathogens, teach aseptic practices. Patients and family members need to learn thorough hand hygiene (handwashing or the use of hand rub) and when to use it (e.g., before and after caring for a family member, before food preparation, before preparing a medication for a family member, and after contacting any body fluids). When patients require dressing changes or the use of syringes and needles, families should be shown how to properly dispose of contaminated items in the home. Most communities have regulations for the disposal of biohazardous waste.

Limiting Specific Risks to Patient Safety

A number of specific safety measures are applicable to patients in the home or health care agency. Take actions to help patients avoid injuries related to falls, the use of restraints and side rails, electrical hazards, and radiation. Special precautions are necessary to prevent injury in patients susceptible to having seizures.

Falls. Easy modifications in the home and health care environment can reduce the risk of falls (Table 36-3). A heavy or debilitated patient in a bed or wheelchair or on a toilet should be properly supported and secured. Side rails may be necessary. Safety bars near toilets, locks on beds and wheelchairs, and call lights are additional safety features found in health care settings (Figures 36-12 and 36-13). Excess furniture and equipment should be removed. Weakened patients should wear rubber-soled shoes or slippers when walking or transferring. For patients who use assistive aids such as canes, crutches, or walkers, it is important to routinely check the condition of rubber tips and the integrity of the aid.

In the health care setting, injuries may occur when patients attempt to address self-care needs independently despite encouragement to call for assistance. One way to minimize the occurrence of such incidents is to check in on patients frequently during the day. A formal routine of nursing rounds, during which nurses visit patients every hour and provide necessary assistance, has been found to decrease the incidence of falls and increase patient satisfaction (Box 36-11).

Figure 36-12 Safety bars beside a toilet and shower.

Figure 36-13 Safety locks on a wheelchair.

BOX 36-11 RESEARCH HIGHLIGHT

Effects of Nursing Rounds

Research Focus

Hospitalized patients often require assistance with basic activities of daily living such as eating, toileting, and ambulating. Patients usually communicate their needs by use of a call light. Not meeting a patient's needs in a timely fashion decreases patient satisfaction and places him or her at greater risk for injury. You play a key role in the prevention of falls and injuries related to falls.

Research Abstract

Meade and colleagues (2006) wanted to know if making nursing rounds every one or two hours would reduce call light usage, increase patient satisfaction, and reduce the frequency of patient falls. During rounds, the following actions were performed for each patient: pain management, toileting, positioning, and placing items such as the call light, telephone, television remote, bed light switch, tissues, and water within reach and the garbage can next to bed. In addition, before leaving the room, the nurse asked, "Is there anything else I can do for you before I leave? I have time while I'm here in the room." The patient was also told that a staff member would be back in one (or two) hours.

A six-week quasi-experimental study was conducted on 27 nursing units in 14 hospitals. Researchers took baseline data on call light usage during the initial two weeks. Performing rounds at set intervals, including specific nursing actions, was associated with statistically significant reduced patient call light usage, increased patient satisfaction, and, in the group receiving rounds hourly, decreased patient falls.

Evidence-Informed Practice

- Nursing rounds performed at set intervals positively affect patient satisfaction and safety and lead to fewer distractions for the staff.
- Nurses' ability to meet patients' needs affects patients' perception of the quality of nursing care.
- Nurses can anticipate patient needs by performing rounds, including specific nursing actions, at one-hour intervals.

► **TABLE 36-3** Measures to Prevent Falls by Older Adults

Measure

Stairs

Install treads with a uniform depth of 22.5 cm and 22.5 cm risers (vertical face of steps).

Install uniform-textured or plain-coloured surfaces on each tread, and mark the edges of treads with a contrasting colour.

Ensure proper lighting of each tread. Block glare from the sun or a light bulb with translucent shades or a screen, or use lower-wattage or nonglare bulbs.

Ensure adequate headroom so that patients do not have to duck to negotiate stairs.

Remove protruding objects from staircase walls.

Maintain outdoor walkways and stairs in good condition and free of holes, cracks, and splinters.

Rationale

If stairs are of uniform size, older adults do not need to continually adjust their vision.

Uniform textures or colour help to decrease vertigo. Marking the edges of treads provides obvious visual cues to end of stairs.

Older adults' vision is unable to adjust quickly to changes in lighting.

Sudden changes in head position may result in dizziness.

Decreased peripheral vision may prevent the patient from seeing an object.

Decreased visual acuity can prevent the patient from seeing any structural defect.

Handrails

Install a smooth but slip-resistant handrail at least 5 cm from wall.

Secure the handrail firmly so that the patient's weight is supported, especially at bottom and top of stairway.

Install grab rails in bathroom near the toilet and tub.

Install an elevated toilet seat with armrests and nonslip strips.

A 5 cm distance allows the patient to grasp the handrail firmly for support.

Older adults have the greatest risk of falling at top and bottom of stairs because their centre of gravity is being shifted and balance is unstable.

These measures enable the patient to have support while rising from a sitting to standing position.

Floors

Ensure that patients wear properly fitting shoes or slippers with a nonskid surface.

Secure all carpeting, mats, and tiles; place nonskid backing under small rugs.

Place bath mats or nonskid, coloured strips on bathtub or shower stall floors and on the floor in front of the toilet.

Secure electrical cords against the baseboards.

Maintain proper illumination inside and outside where the patient moves and walks.

Such footwear reduces the chances of slipping.

A sudden slip may cause dizziness and an inability to regain balance.

Wet surfaces increase the risk of falling.

This measure prevents tripping.

This measure reduces the risk of falling due to eye strain.

Health Care Facility Orientation

Place disoriented patients in a room near the nurses' station.

Supervise confused patients closely.

Show the patient how to use the call light at the bedside and in the bathroom, and place it within easy reach.

Place bedside tables and overbed tables close to the patient.

Remove clutter from bedside tables, hallways, bathrooms, and grooming areas.

Leave one side rail up and one down on the side where the oriented and ambulatory patient gets out of bed.

Proximity provides for more frequent observation by nursing staff.

Confused patients often attempt to wander out of bed or the room. The location and use of the call light are essential to patient safety.

This measure prevents the patient from searching or overreaching for items such as eyeglasses, dentures, a hearing aid, or the telephone.

This measure eliminates potential hazards and promotes patient independence.

The patient can use the side rail for support when getting in and out of bed and to position self once in bed.

Transport

Lock beds and wheelchairs when transferring a patient from a bed to a wheelchair or back to bed.

Place side rails in the up position and secure safety straps around the patient when transporting him or her by stretcher.

The locks provide stability and support during transfer.

This measure prevents the patient from rolling off the stretcher.

Adapted from Chang, J. T., Morton, S. C., Rubenstein, L. Z., Mojica, W. A., Maglione, M., Suttrop, M. J., Roth, E. A., & Shekelleet, P. J. (2004). Interventions for the prevention of falls in older adults: Systematic review with meta-analysis of randomized clinical trials. *British Medical Journal*, 328, 680.

The risk of injury in the home may be reduced by removing all obstacles from halls and other heavily travelled areas. Necessary objects such as clocks, glasses, tissues, and medications should remain on bedside tables within reach of the patient but out of the reach of children. Care should also be taken to ensure that end tables are secure and have stable, straight legs. Nonessential items should be placed in drawers to eliminate clutter. If small area rugs are used, they should be secured with a nonslip pad or skid-resistant adhesive strips. Carpeting on the stairs should be secured with carpet tacks.

Restraints. A restraint is a physical, chemical, or environmental means of controlling an individual's behaviour or actions (College of Nurses of Ontario, 2009b). The use of restraints is controversial as they have been associated with negative consequences including injury and death. Familiarize yourself with the legal aspects of restraint use. You must also follow guidelines and standards provided by your provincial nursing governing body as well as policies and procedures set by your clinical practice setting. A least-restraint approach is recommended to ensure highest-quality care. This approach ensures that all alternative interventions are attempted before moving to the use of restraints, and that the form of restraint selected is the one that addresses a patient's needs in the least restrictive way (College of Nurses of Ontario, 2009b).

It is imperative that you try alternative measures (Box 36-12) as the application of a restraint should always be a measure of last resort. The use of restraints must be guided by a patient's needs and requires a thorough assessment by you and other

► BOX 36-12 Alternatives to Restraints

- Orient patients and families to their environment; explain all procedures and treatments.
- Provide companionship and supervision; use trained sitters or adjust staffing.
- Offer diversionary activities, such as listening to music or having something to hold; enlist support and input from the family.
- Assign confused or disoriented patients to rooms near the nurses' station; observe these patients frequently.
- Use calm, simple statements and physical cues as needed.
- Use de-escalation, time-outs, and other verbal intervention techniques when managing aggressive behaviours.
- Provide appropriate visual and auditory stimuli (e.g., family pictures, a clock, or a radio).
- Remove cues that promote leaving (e.g., sight of elevators, stairs, or street clothes).
- Promote relaxation techniques and normal sleep patterns.
- Institute exercise and ambulation schedules as allowed by patients' conditions; consult a physiotherapist for mobility and exercise programs.
- Attend to the patient's toileting, food, and fluid needs.
- Camouflage IV lines with clothing, a stockinette, or a Kling dressing.
- Evaluate all medications the patients are receiving, and ensure effective pain management.
- Reassess the physical status of patients, and review laboratory findings connected with their health.

Source: Adapted from Joint Commission Resources. (2006). *Strategies for avoiding restraint related errors*. Retrieved from <http://www.jcrrc.com>; and American Nurses Association. (2006). members of the multidisciplinary team involved in the patient's care. A restraint-use algorithm provides evidence-informed guidelines for determining whether a restraint is appropriate and what interventions might be used (Figure 36-14).

The use of any type of restraint involves a psychological adjustment for the patient and family. If restraints must be used, assist family members and the patient by explaining the purpose of the restraints, the patient's expected care while restrained, the precautions to be taken to avoid injury, and the temporary and protective aspects of restraints. Informed consent from family members may also be required before using restraints. The nursing story in Box 36-13 demonstrates family involvement in a decision about restraint.

A **physical restraint** immobilizes a patient or a patient's extremity (College of Nurses of Ontario, 2009b). The optimal goal with all patients is to avoid the use of physical restraints, and alternatives must always be considered. However, patients

BOX 36-13 NURSING STORY

David's Mittens

Katherine has been caring for David, a six-month-old boy who has been hospitalized for several weeks. David has a complex health problem and is currently experiencing severely dry, itchy skin associated with his illness. Katherine has noticed that anti-itch medications decrease David's discomfort but do not eliminate the itch entirely. As a result, he continues to scratch, and even with regularly trimmed nails, he has scratched himself hard enough to cause bleeding. David's mother plays with him to distract him from the itch, and when he tries to scratch, she gently holds his hands. However, she cannot be with David at all times in the hospital. Another concern is that David scratches his skin while sleeping.

Katherine discusses the situation with David's mother, and they decide to use mitten restraints to protect David's skin. They agree to use the restraints when David sleeps and when he is awake and alone. Katherine notes this decision in David's care plan, implements the required documentation according to her hospital's policy, and applies the restraints according to the proper procedure.

Katherine returns to work after two days off and finds that David's restraints have been applied improperly, leaving him at risk for injury. Recognizing that this may reflect a knowledge gap on the part of staff involved in David's care, she posts the instructions for the proper application of restraints at David's bedside, where they will be easily seen. Katherine also notes in David's care plan the need for proper use of restraints.

The need for the mitten restraints is reassessed daily, including feedback from David's mother. Volunteers visit him at the times he is most likely to be awake and alone, thus minimizing the need for restraints. Regular assessment and documentation are maintained according to the hospital's protocol. With continued treatment of David's illness, his skin condition improves, and within five days, the mitten restraints are discontinued.

Katherine and David's mother are pleased to see that David sustained no further scratch injuries once the restraints were implemented. David's mother states that although she does not like to see her baby restrained, she knows it is in his best interest. She appreciates the volunteers' efforts to spend time with David as well as everyone's diligence in applying the restraints properly. Katherine reflects upon this situation and decides that the next time she implements the use of restraints, she will post instructions for their use at the bedside immediately upon implementation.

Figure 36-14 Algorithm for the use of restraints. **Source:** Developed from Ledford, L., & Mentals, J. (Written 1996; revised November 2005). "Restraints"—A research-based protocol. who are at risk for injury to self or others may need physical restraints temporarily. Alternative forms of restraint should always be considered as well. Physical restraints do not prevent falls and may actually increase the severity of an injury from a fall (Registered Nurses' Association of Ontario, 2005).

Whenever patients are physically restrained, there is a natural tendency for them to try to remove the restraint, and this can lead to injury. Restrained patients can easily become entangled in a restraint device when attempting to get out of it. In some cases, death has resulted from strangulation or asphyxiation. As a result, long-term care facilities and many health care facilities have banned the use of the jacket (vest) restraint. The use of any physical restraint is also associated with serious complications, including pressure ulcers; constipation; pneumonia; urinary and fecal incontinence; and

urinary retention. Contractures, nerve damage, and circulatory impairment are also potential hazards. In addition, restrained patients can experience humiliation, fear, anger, and a loss of self-esteem.

safety alert Routine assessment of a patient in a physical restraint is critical to prevent injury. The restraint must be moved and the patient repositioned at regular intervals, according to the agency's policy. Restraints should be used only after other alternatives have been tried, and the least restrictive method of restraint should be used. The use of restraints must be part of the patient's medical treatment. Restraints are considered a short-term intervention, and once they have been applied, regular assessments are needed to determine whether they should be continued. All assessments and interventions must be clearly documented according to the agency's policy.

For legal purposes, know the agency's policy and procedures for the appropriate use and monitoring of physical restraints. The use of a restraint must be clinically justified and be a part of the patient's prescribed medical treatment and care plan. A physician's order may be required, depending on provincial or territorial legislation and agency policy—in some settings, nurses may order restraints. Requirements for ordering restraints may vary depending on the circumstances of a patient's situation and the type of restraint needed; you must comply with the agency's policies. Assessment of patients who are restrained must be ongoing. Proper documentation, including the behaviours that necessitated the application of restraints, the procedure used in restraining, the condition of the body part restrained (e.g., circulation to the patient's hand), and the evaluation of the patient response, is essential. Remove the restraints periodically and assess the patient to determine if the restraints continue to be needed.

Skill 36-1 includes guidelines for the proper use and application of restraints. Use of restraints must meet the following objectives:

- Reduce the risk of patient injury
- Prevent the interruption of therapy, such as traction, IV infusion, nasogastric tube feeding, or Foley catheterization
- Prevent the confused or combative patient from removing life-support equipment
- Reduce the risk of injury to others by the patient

In keeping with current trends toward health promotion, improved assessment techniques and modifications of the environment are offered as alternatives to physical restraints. An **Ambularm** is a device worn on the leg that signals when the leg is in a dependent position, such as over the side rail or on the floor (Figure 36-15). The **Bed-Check** bed exit alarm system (Figure 36-16) uses a weight-sensitive sensor mat that can be placed on the patient's mattress or chair. This device sounds an audible alarm at the bedside when pressure is released off the sensor mat. Such devices are useful for patients who tend to climb out of bed unassisted but are in danger of falling. Other alarms can be placed on doors to alert staff or family members when a confused patient, prone to wandering, opens a door.

Another alternative form of restraint is the Posey Bed Enclosure (Figure 36-17), a soft-sided, self-contained enclosed

bed. It allows for freedom of movement and thus reduces the side effects caused by physical restraints such as pressure ulcers and loss of dignity. The Posey Bed Enclosure works well for patients who are restless and unpredictable, cognitively impaired, and at risk for injury if they were to fall or get out of bed, such as patients on anti-coagulant therapy at risk for intracranial bleed. The bed may also be a safer alternative to side rails.

A long-term care setting may be designed to include **environmental restraints**, such as locked nursing units. Residents

► SKILL 36-1 Applying Physical Restraints

Delegation Considerations

The application of physical restraints may be delegated to trained unregulated care providers (UCPs). Review the following with the UCP:

- Ask the UCP to inform you of any skin redness or excoriation, constriction of circulation under the restraint, or change in the patient's breathing.
- Review the correct placement of the restraint with the UCP and ask him or her to request assistance if the patient has any mobility restrictions that might affect how to remove or reapply a restraint.
- Instruct the UCP when and how to change the patient's position and to provide range-of-motion exercises, skin care, toileting, and opportunities for socialization.

However, you are always responsible for the assessment of a patient's safety needs, selection of appropriate alternative interventions, evaluation of the effectiveness of restraint, and ongoing assessment to prevent complications of restraint use.

Equipment

- Proper restraint: mitten, belt, extremity
- Padding (if needed)

Procedure

STEPS

1. Assess whether the patient needs a restraint. Does the patient continually try to interrupt needed therapy? Is the patient at risk for injuring self or others?
2. Assess the patient's behaviour, such as confusion, disorientation, agitation, restlessness, combativeness, or inability to follow directions. Consult with a gerontological nurse specialist if available.
3. Review your agency's policies regarding restraints. Consider the purpose, type, location, and duration of restraint. Determine whether signed consent for the use of restraint is needed.
4. Review manufacturer's instructions before entering the patient's room. Determine the most appropriate size restraint.
5. Perform hand hygiene and gather equipment.
6. Introduce yourself to the patient and family. Assess their feelings about restraint use. Explain that restraint is temporary and designed to protect the patient from injury.
7. Inspect the area where the restraint is to be placed. Assess the condition of skin underlying where the restraint is to be applied.
8. Approach the patient in a calm, confident manner. Check the patient's identification using two identifiers. Explain what you plan to do.
9. Adjust the bed to proper height, and lower the side rail on the side of patient contact.
10. Provide privacy. Make sure the patient is comfortable and in proper body alignment. Drape patient as needed.
11. Pad the skin and bony prominences (if necessary) before applying restraints.
12. Apply the appropriate-size restraint, making sure it is not over an IV line or other device (e.g., dialysis shunt) and that it does not cover the patient's identification or allergy bracelet.

RATIONALE

- Restraints are used only when other measures have failed to prevent the interruption of therapy such as traction, IV infusions, or nasogastric tube feedings; to prevent a confused or combative patient from self-injury by falling out of bed or a wheelchair; to prevent a patient from removing a urinary catheter, surgical drain, or life-support equipment; and to reduce the risk of injury to others by the patient.
- If patient's behaviour continues despite attempts to eliminate the cause of behaviour, use of physical restraint may be necessary.
- The least restrictive type of restraint must be ordered. A physician's order may be necessary—check provincial or territorial legislation and agency policy. Because restraints limit the patient's ability to move freely, you must make clinical judgements appropriate to the patient's condition and the agency policy.
- You should be familiar with all devices used for patient care and protection. Incorrect application of a restraining device may result in patient injury or death.
- Reduces transmission of microorganisms; promotes organization.
- Helps minimize patient anxiety during the application of the device, and helps minimize family concern during the maintenance of restraint.
- Restraints may compress and interfere with the functioning of devices or tubes. Inspection provides baseline assessment data regarding skin integrity.
- Reduces patient anxiety and promotes cooperation.
- Allows you to use proper body mechanics and prevent injury.
- Privacy protects self-esteem. Proper body alignment promotes comfort and prevents contractures and neurovascular injury.
- Padding reduces friction and pressure on skin and underlying tissues.
- IV lines and other therapeutic devices may become occluded. The patient's ID and allergy information must always be visible and accessible.

video

A. Belt restraint: This device secures the patient to a bed or stretcher. Apply it over the patient's clothes or gown. Remove wrinkles from the front and back of the restraint while placing it around the patient's waist. Bring ties through slots in the belt. Avoid placing the belt across the chest or too tightly across the abdomen (see Step 12A illustration).

- Restrains centre of gravity and prevents the patient from rolling off the stretcher or sitting up while on stretcher or from falling out of bed. Tight application may interfere with ventilation.

Step 12A Belt restraint is tied to the bed frame and to an area that does not cause the restraint to tighten when the side rail is raised or lowered. **Source:** Sorrentino, S. A. (2004). *Mosby's textbook for nursing assistants* (7th ed., p. 193). St Louis, MO: Mosby.

B. Extremity (ankle or wrist) restraint: This restraint is designed to immobilize one or all extremities. Commercially available limb restraints are composed of sheepskin or foam padding (see Step 12B illustration). The limb restraint is wrapped around the wrist or ankle with the soft part toward the skin and is secured snugly in place with Velcro straps.

- Maintains immobilization of the extremity to protect the patient from injury from a fall or accidental removal of a therapeutic device (e.g., IV tube or Foley catheter). Tight application may interfere with circulation.

Step 12B Extremity restraint being applied to the wrist.

C. Mitten restraint: This thumbless mitten device is used to restrain the patient's hands (see Step 12C illustration). Place a hand in the mitten, being sure the mitten end is brought all the way over the wrist.

D. Elbow restraint: This piece of fabric with slots has tongue blades placed so that the elbow joint remains rigid (see Step 12D illustration).

- Prevents patients from dislodging invasive equipment, removing dressings, or scratching, yet allows greater movement than a wrist restraint.
- Commonly used with infants and children to prevent elbow flexion (e.g., when an IV line is in place).

Step 12C Mitten restraint.

Step 12D Elbow restraint.

► SKILL 36-1 Applying Physical Restraints—cont'd

video

E. **Mummy restraint:** The mummy restraint consists of a blanket or sheet. It is opened on the bed or crib with one corner folded toward the centre. The child is placed on the blanket with shoulders at the fold and feet toward the opposite corner (see Step 12E-1 illustration). With the child's right arm straight down against body, the right side of blanket is pulled firmly across the right shoulder and chest and secured beneath the left side of body (see Step 12E-2 illustration). The left arm is placed straight against the body, and the left side of the blanket is brought across the shoulder and chest and locked beneath child's body on the right side (see Step 12E-3 illustration). The lower corner is folded and brought over the body and tucked or fastened securely with safety pins (see Step 12E-4 illustration).

- Maintains short-term restraint of small child or infant for an examination or treatment involving the head and neck. Effectively controls movement of torso and extremities.

Step 12E Mummy restraint.

13. Attach restraints to the bed frame, which moves when the head of the bed is raised or lowered (see Step 13 illustration).

- Patient may be injured if restraint is secured to side rail and it is lowered.

Step 13 Tie restraint strap to the bed frame.

Critical Decision Point: Do not attach end of restraint to side rails.

Continued

video

14. Secure restraints with a quick-release tie (see Step 14 illustration). Do not tie in a knot.
15. Insert two fingers under the secured restraint (see Step 15 illustration).

Step 14 The Posey quick-release tie. **Source:** Courtesy JT Posey Co., Arcadia, CA.

- Allows for quick release in an emergency.
- A tight restraint may cause constriction and impede circulation. Checking for constriction prevents neurovascular injury.

Step 15 Place two fingers under the restraint to check tightness.

16. The proper placement of the restraint, skin integrity, pulses, temperature, colour, and sensation of the restrained body part should be assessed at least every hour or according to your agency's policy.
 17. Restraints should be removed at regular intervals (see agency policy). If the patient is violent and noncompliant, remove one restraint at a time or have staff assist while removing the restraints. The patient should not be left unattended at this time.
 18. Secure a call light or intercom system within the patient's reach.
 19. Leave the bed or chair with wheels locked. The bed should be in its lowest position.
 20. Perform hand hygiene.
 21. Reassess the patient's status and needs.
 - A. Inspect the patient for any injuries, including all hazards of immobility, while restraints are in use.
 - B. Observe IV catheters, urinary catheters, and drainage tubes to ensure that they are positioned correctly and that therapy remains uninterrupted.
 - C. Regularly reassess the patient's need for continued use of the restraint (for medical or surgical reason) with the intent of discontinuing the restraint at the earliest possible time (see agency-specific policy).
 - D. Provide appropriate sensory stimulation and reorient patient as needed.
- Frequent assessments prevent complications, such as suffocation, skin breakdown, and impaired circulation.
 - Provides opportunity to change patient's position and perform full range of motion, toileting, and exercise and to provide food or fluids.
 - Allows patient, family, or caregiver to obtain assistance quickly.
 - Locked wheels prevent the bed or chair from moving if the patient attempts to get out. If the patient falls when the bed is in lowest position, the chances of injury are reduced.
 - Reduces transmission of microorganisms.
 - Patient should be free of injury and not exhibit any signs of immobility complications.
 - Reinsertion can be uncomfortable and can increase the risk of infection or interrupt therapy.
 - Use of restraints should be seen as a temporary measure and discontinued as soon as possible (College of Nurses of Ontario, 2009b).
 - Use of restraints can further increase disorientation.

Unexpected Outcomes

Patient has signs of impaired skin integrity

Related Interventions

- Assess skin and provide appropriate therapy.
- Notify the physician and reassess the need for continued use of the restraint.
- Ensure the correct application of restraint. Pad the skin under the restraint, and remove restraint more often.

► SKILL 36-1 Applying Physical Restraints—cont'd

Patient has altered neurovascular status in an extremity (cyanosis, pallor, coldness of skin, or complaints of tingling, pain, or numbness)

Patient is increasingly confused, disoriented, or agitated

Patient escapes from restraint device and suffers fall or injury

- Remove the restraint immediately, stay with the patient, and notify the physician.
- Protect the extremity from further injury (e.g., pressure from tubing or encumbrance, positioning).
- Identify the reason for this change in behaviour, and attempt to eliminate the cause.
- Attempt a restraint alternative.
- Attend to the patient's immediate physical needs, and inform the physician.
- Reassess the type of restraint used, the correct application, and if alternatives can be used.

Recording and Reporting

- Record behaviours that place patient at risk for injury.
- Describe restraint alternatives attempted and patient's response.
- Record patient's and family's understanding of and consent to restraint application.
- Record type and location of the restraint and time applied.
- Record time of assessments and releases.
- Document the patient's behaviour after the application of the restraint.
- Document specific assessments related to orientation, oxygenation, skin integrity, circulation, and positioning.
- Describe the patient's response when restraints were removed.

Home Care Considerations

- Plan care with family. If possible, use of an Ambularm may free patient from physical restraints.
- Instruct family members (or other caregivers) in the use of alternatives to restraints (see Box 36-12).
- A physical restraint may require a physician order. The restraint should not be sent home with family unless the device is needed to protect the patient from injury. If physical restraints are necessary, the family members (or other caregivers) must be instructed in its proper application, the care needed while in restraints, and the complications for which to look. Also inform caregivers whom to contact if any abnormal findings occur.
- A patient who needs to be restrained in bed should have a hospital bed and will require constant supervision in the home.

with dementia may be at risk for injury if they wander away from their unit or building. A locked nursing unit can be designed to permit individuals the freedom to wander safely around their unit and can include exits to secure, enclosed outdoor spaces when weather permits. A locked unit is still a form of restraint and should be implemented only after alternatives to restraint have proven unsuccessful.

In some situations, chemical restraints may be indicated. **Chemical restraint** is defined as “any form of psychoactive medication used, not to treat illness, but to intentionally inhibit a particular behaviour or movement” (College of Nurses of Ontario, 2009b, p. 4). For example, it may be necessary to sedate a patient who is consistently pulling out a nasogastric tube. As with any other restraint, chemical restraints should be implemented only after nonrestraining measures (e.g., distraction, use of a sitter) have proven ineffective and with the informed consent of the patient or their substitute decision maker. Proper adherence to medication administration guidelines is vital to the safe use of chemical restraints, and the patients' response to and need for these medications must be assessed on a regular basis.

Side Rails. Side rails may help to increase a patient's mobility and stability when in bed or when moving from the bed to a chair. Side rails also help prevent the unconscious patient from falling out of bed or off a stretcher (Figure 36-18). However, raised side rails that cannot be opened by the patient are considered a restraint (College of Nurses of Ontario, 2009b). The use of side rails for a disoriented patient may cause more confusion and further injury. A confused patient who is determined to get out of bed may attempt to climb over the side rail

Figure 36-18 Side rails in the up position on a stretcher.

or climb out at the foot of the bed, often resulting in a fall or injury. Nursing interventions to reduce a patient's confusion should first focus on the cause of the confusion. Frequently, a patient's attempt to explore his or her environment or to self-toilet is mistaken as confusion. A thorough assessment is essential. Whenever side rails are used, the bed should be maintained in the lowest position possible.

Electrical Hazards. Electrical equipment must be maintained in good working order and should be grounded. The third (longer) prong in an electrical plug is the ground. Theoretically, the ground prong carries any stray electrical current back to the ground—hence, its name. The other two prongs

* BOX 36-14 PATIENT TEACHING

Prevention of Electrical Hazards in the Home

Objective

- Patient will recognize electrical hazards in the home and eliminate them.

Teaching Strategies

- Discuss grounding appliances and other equipment.
- Provide examples of common hazards: frayed cords, damaged equipment, and overloaded outlets.
- Discuss guidelines to prevent electrical shocks:
 - Use extension cords only when necessary, and use electrical tape to secure the cord to the floor where it will not be stepped on.
 - Do not run wires under carpeting.
 - Teach the patient to grasp the plug, not the cord, when unplugging items.
 - Teach the patient to keep electrical items away from water.
 - Teach the patient not to operate equipment with which he or she is unfamiliar.
 - Teach the patient to disconnect items before cleaning them.

Evaluation

- Have patient list electrical hazards existing in the home.
- Review with the patient the steps he or she will take to eliminate these hazards.
- Reassess the home after the patient has had an opportunity to eliminate the hazards.

Knowledge

- Effect of new medication therapies on the patient's cognitive/motor functioning
- Characteristics of safe and unsafe patient behaviours
- Characteristics of a safe environment

Experience

- Previous patient responses to planned nursing therapies to improve the patient's safety (e.g., what worked and what did not work)

Evaluation

- Reassess the patient for the presence of physical, social, environmental, or developmental risks
- Determine if changes in the patient's care resulted in increased threats to safety
- Ask if the patient's expectations are being met

Standards

- Use established expected outcomes to evaluate the patient's response to care (e.g., reduction in modifiable risk factors)

Qualities

- Display humility when rethinking unsuccessful interventions designed to promote patient safety
- Demonstrate responsibility for accurately evaluating nursing interventions designed to promote the patient's safety

Figure 36-19 Critical thinking model for safety evaluation.

carry the power to the piece of electrical equipment. Improperly grounded or malfunctioning electrical equipment increases the risks of electrical injury and fire. Educating both the patient and the family can reduce the risk for electrical hazards in the home environment (Box 36-14).

If a patient receives an electrical shock in a health care setting, immediately determine whether the patient has a pulse. If the patient has no pulse, cardiopulmonary resuscitation should be initiated and emergency personnel should be notified. If the patient has a pulse and remains alert and oriented, quickly obtain vital signs and assess the skin for signs of thermal injury. The patient's physician must be notified. If an electrical shock occurs in the home, follow the same procedure but have the patient go to the emergency department and then notify the patient's physician.

Seizures. Patients with a history of seizures and those who have experienced some form of neurological injury or metabolic disturbance may be at risk for a seizure. **Seizure precautions** are nursing interventions during and after a seizure and include protecting the patient from traumatic injury, positioning the patient for adequate ventilation and drainage of oral secretions, and providing privacy and support following the seizure (Skill 36-2). It is important that you observe the patient carefully before, during, and after the seizure and document assessments accurately.

Radiation. Radiation is a health hazard in the health care setting and the community. Radiation and radioactive materials are used in the diagnosis and treatment of patients. Hospitals have strict guidelines on the care of patients who are receiving radiation and radioactive materials. Familiarize

yourself with the agency's established protocols. Exposure to radiation can be reduced by limiting the time spent near the source, making the distance from the source as great as possible, and using shielding devices such as lead aprons. Staff working near radiation wear devices that track accumulative exposure to radiation.

The community can be at risk for radiation exposure if there has been incorrect disposal and transportation of radioactive waste products. The Canadian Nuclear Safety Commission ensures that the disposal of radioactive waste does not pose a danger for the public or the environment. If a radioactive leak occurs, this commission institutes measures to prevent the exposure of surrounding neighbourhoods, to clean up radioactive leaks as quickly as possible, and to ensure that injured parties receive prompt medical care.

❖ Evaluation

Patient Care

The components of critical thinking are applied to the evaluation step of the nursing process (Figure 36-19). The actual care delivered by the health care team is evaluated on the basis of expected outcomes. If the patient's goals have been met, the nursing interventions can be considered effective and appropriate. If not, determine whether new risks to the patient have developed or whether previous risks remain. The patient and family need to participate to find permanent ways to reduce risks to safety. Continually assess the patient's and family's

► SKILL 36-2 Seizure Precautions

Delegation Considerations

Assessment of a patient's need for seizure precautions cannot be delegated to an unregulated care provider (UCP). If a seizure occurs, you must constantly assess the patient's airway patency, adequacy of breathing, and circulatory status. Clinical judgements must be made quickly. The tasks of setting up seizure precautions and protecting patients at risk for seizures may be delegated to a UCP:

- Inform the UCP about a patient's history of seizures and factors that may trigger a seizure.
- Caution the UCP against any attempt to restrain the patient's extremities or place anything in the patient's mouth during a seizure.

Procedure

STEPS

1. Assess seizure history, noting the frequency of seizures, presence of aura, and sequence of events, if known. Assess for medical and surgical conditions that may lead to seizures or exacerbate existing seizure condition. Assess medication history.
2. Inspect the patient's environment for potential safety hazards if risk for seizure exists, such as a bedside stand or table, an IV pole, or other medical equipment.
3. Perform hand hygiene and prepare bed with padded side rails and headboard. Set the bed in the low position, and place the patient in side-lying position when possible (see Step 3 illustration).
4. For patients with a history of seizures ensure that items such as an airway (see Step 4 illustration), suction apparatus, disposable gloves, and pillows are visible in the hospital setting for immediate use.

Equipment

- Oral airway
- Padding for side rails and headboard
- Suction machine, oral suction equipment
- Disposable gloves

RATIONALE

- Enables you to anticipate the onset of seizure activity. Seizure medications must be taken as prescribed and not stopped suddenly because this may precipitate seizure activity.
- Prevents patient from sustaining injury by striking head or body on furniture or equipment.
- Minimizes risks associated with seizure activity.
- Ensures a prompt, organized intervention.

Step 4 Oral airways.

Step 3 Provide patient privacy. Put bed in lowest position with side rails up and padded. Position patient in side-lying position, with pillow under head, and loosen clothing.

5. When a seizure begins, position patient safely. If patient is standing or sitting, guide the patient to floor and protect his or her head by cradling it in your lap or placing a pillow under the head. Clear the surrounding area of furniture. If the patient is in bed, raise the side rails, add padding, and put the bed in low position.

- Protects patient from traumatic injury, especially a head injury.

Continued

► SKILL 36-2 Seizure Precautions—cont'd

6. Provide privacy.
 7. If possible, turn patient on side, with head flexed slightly forward.
 8. Do not restrain patient. Loosen patient's clothing.
 9. Do not put anything into the patient's mouth such as fingers, tongue depressor, or medicine.
- Embarrassment is common after a seizure, especially if others witness the seizure.
 - Prevents tongue and dentures from blocking the airway and promotes drainage of secretions, thus reducing the risk of aspiration.
 - Prevents musculoskeletal injury.
 - Putting something in the patient's mouth could result in injury to the patient.

Critical Decision Point: Objects in the patient's mouth could cause injury to the jaw, tongue, or teeth and cause stimulation of the gag reflex, causing vomiting, aspiration, and respiratory distress (Epilepsy Canada, 2005).

10. Stay with the patient, observing the sequence and timing of seizure activity.
 11. After the seizure is over, explain what happened and answer the patient's questions. Foster an atmosphere of acceptance and respect.
 12. Following the seizure, assist the patient to a position of comfort in bed with padded side rails up and the bed in low position. Place a call light within reach, and provide a quiet, nonstimulating environment. Perform hand hygiene before leaving the room.
- Continued observation is necessary to ensure adequate ventilation during and following seizure activity. Accurate, specific observations will assist in the documentation, diagnosis, and treatment of the seizure disorder.
 - Informing patients of the type of seizure activity experienced assists them in participating knowledgeably in their care.
 - Provides for continued safety. Patients are often confused and sleepy following a seizure.

Status Epilepticus

For a patient experiencing status epilepticus, the following actions are required:

13. Put on disposable gloves and insert an oral airway (see Step 4 illustration) when the jaw is relaxed between seizure activities. Hold the airway with curved side up, insert downward until airway reaches back of throat, then rotate and follow natural curve of the tongue. Do not place fingers near or in the patient's mouth.
 14. Access oxygen and suction equipment. Prepare for IV insertion.
 15. Use pillows or pads to protect the patient from injuring self.
- Prevents transmission of infection. Patient is in continual seizure state and requires oral airway to ensure airway patency. Patient may inadvertently bite fingers during a seizure if caution is not used.
 - Intensive monitoring and treatment are required for this medical emergency.
 - Traumatic injury is avoided.

Unexpected Outcomes

Patient suffers traumatic injury

Related Interventions

- Continue to protect the patient from further injury.
- Notify the physician immediately.
- Ensure the environment is free of safety hazards.

Recording and Reporting

- Record the timing of seizure activity and the sequence of events. Record the presence of aura (if any), level of consciousness, posture, colour, movements of extremities, incontinence, and patient's status following the seizure.
- Document patient's response and expected or unexpected outcomes.
- Report to the physician immediately as seizure begins. Status epilepticus is an emergency situation requiring immediate medical management.

Home Care Considerations

- Communicate with the patient and family to identify precipitating factors.
- Teach the family to care for the patient during a seizure.
- The patient's home should be assessed for environmental hazards in light of the seizure condition.
- Provide the family with guidelines to detect status epilepticus.
- Until a seizure condition is well controlled (usually for at least one year), the patient should not take a tub bath or engage in activities such as swimming unless a knowledgeable family member is present. Driving may also be restricted during this time.
- The patient should wear a medical alert bracelet or tag and have an identification card noting the presence of a seizure disorder and listing the medications taken.
- Referral to a support group or Epilepsy Canada may help to improve the patient's self-esteem and coping ability.

need for additional support services, such as home care, physiotherapy, counselling, and further teaching.

Patient Expectations

When you have developed a good relationship with a patient and the patient feels safe and secure in the environment, he or she will most likely demonstrate satisfaction. You must determine, however, if patient expectations have been met. Is the patient satisfied with any changes made to the environment? Does the patient believe that his or her safety is ensured? If patient expectations have not been met, you must reassess not only the patient and the environment, but also the patient's expressed desires.

❖ KEY CONCEPTS

- A safe environment is essential to promoting, maintaining, and restoring health.
- Nurses must maintain their own safety in order to provide safe care to patients.
- In the community, a safe environment is one in which basic needs are achievable, physical hazards are reduced, the transmission of pathogens is reduced, pollution is controlled, and sanitation is maintained.
- In a health care agency, a safe environment is one that minimizes falls, patient-inherent accidents, procedure-related accidents, and equipment-related accidents.
- A factor that reduces atmospheric oxygen is the presence of high carbon monoxide levels, which may result from an improperly functioning furnace.
- Prolonged exposure to extreme environmental temperatures can cause patient injury or even death.
- The reduction of physical hazards in the environment includes providing adequate lighting, decreasing clutter, and securing the home.
- The transmission of pathogens is reduced through medical and surgical asepsis, immunization, adequate food sanitation, insect and rodent control, and the appropriate disposal of human waste.
- Children less than five years of age are at the greatest risk for home accidents that may result in severe injury and death.
- The school-aged child is at risk for injury at home, at school, and while travelling to and from school.
- Adolescents are at risk for injury from automobile accidents, suicide, and substance abuse.
- Threats to an adult's safety are frequently associated with lifestyle habits.
- Risks of injury for older patients are directly related to the physiological changes of the aging process; falls are the greatest cause of accidental injury in older adults.
- By incorporating critical thinking skills in the application of the nursing process, you assess the patient and the environment to determine risk factors for injury; cluster risk factors; formulate a nursing diagnosis; and plan specific interventions, including patient education.
- Nursing interventions for promoting safety are individualized for developmental stage, lifestyle, and environment.
- Nursing interventions are developed to modify the environment for protection from falls, fires, poisoning, and electrical hazards.
- The expected outcomes include a safe physical environment, a patient whose expectations have been met and who is

knowledgeable about safety factors and precautions, and a patient free of injury.

❖ CRITICAL THINKING EXERCISES

1. Mrs. Santiago, who is 88 years old and has been functioning independently at home, was recently admitted to the hospital. Through your admission assessment, you learn that she experiences urinary frequency and urgency and occasional dizziness. When you perform the "Get up and Go" test, you find that she can get up on her own successfully after multiple attempts. Use the Hendrich II Fall Risk Model (see Table 36-1) to determine Mrs. Santiago's risk for a fall, and design specific interventions to ensure her safety in the hospital.
2. Mrs. Patel, a 76-year-old long-term care resident with Alzheimer's disease, has been refusing food and fluids for the past month. The family has agreed to the placement of a nasogastric tube to improve her fluid and nutritional statuses. Shortly after the first tube feeding was started, Mrs. Patel became more restless, and she has been picking at the tube.
 - a. What might be precipitating Mrs. Patel's behaviour of picking at the tube?
 - b. What approaches can be used to eliminate interference with the treatment?
 - c. If a restraint is necessary to avoid the disruption of therapy, what interventions are required to ensure the patient's safety while in restraints?
3. A family member of a patient reports that, just a few minutes ago, a lit cigarette dropped on the patient's mattress but that the small fire was put out. What actions are needed to ensure the safety of this patient?

❖ REVIEW QUESTIONS

1. Accidental injuries are the leading cause of death for which age group?
 1. 1 to 12 months
 2. 1 to 34 years
 3. 45 to 64 years
 4. 65 years and over
2. Adolescents are at a greater risk for injury from
 1. Poisoning, drowning, motor vehicle accidents
 2. Motor vehicle accidents, suicide, and substance abuse
 3. Home accidents, motor vehicle accidents, fire
 4. Falls, suicide, drowning
3. The physiological changes caused by aging increase the older patient's risk for
 1. Falls
 2. Suicide
 3. Alcoholism
 4. Seizures
4. WHMIS is a system to control hazardous substances in the workplace and includes
 1. Environmental interventions and cautionary labelling of products
 2. Worker education programs and the provision of MSDSs
 3. Patient education programs and worker education programs
 4. Risk assessment and the provision of MSDSs

5. Medication and fluid administration errors and the improper application of external devices are examples of
 1. Patient-inherent accidents
 2. Procedure-related accidents
 3. Equipment-related accidents
 4. Environmental-related accidents
6. You must always use a mechanical lift to move a heavy patient when
 1. You are by yourself
 2. The patient can bear weight on one leg
 3. The patient is bigger than you are
 4. The patient cannot bear weight on either leg
7. Which of the following statements about restraints is *not* true?
 1. Restraints are used only after other alternatives have been tried.
 2. The least restrictive method of restraint should be used.
 3. Restraints are considered a long-term intervention.
 4. If a restraint is used, it must be part of the patient's medical treatment.
8. When teaching parents about responding to poisoning in children, you should instruct them to
 1. Give oral fluids
 2. Induce vomiting
 3. Call the local poison control centre
 4. Drive the child to the emergency department
9. All of the following are acceptable alternatives to the use of restraints, *except*
 1. Attending to needs for toileting, food, and liquid
 2. Offering diversionary activities, such as music or something to hold
 3. Camouflaging IV lines with clothing or a stockinette
 4. Ensuring that a family member is with the patient at all times

✦ RECOMMENDED WEB SITES

Canada Safety Council: <http://canadasafetycouncil.org/>

The Canada Safety Council is a national, nongovernmental, charitable organization dedicated to providing safety education. Its mission is to reduce preventable deaths and injuries in public and private places throughout Canada.

Canadian Patient Safety Institute: <http://www.patientsafetyinstitute.ca/English/Pages/default.aspx>

Part of Health Canada, the Canadian Patient Safety Institute has been a leader in addressing patient safety issues in Canadian health care agencies. This Web site provides links to various topics relevant to promoting patient safety.

DriveABLE: <http://driveable.com/>

This Web site is a useful resource for nurses working with patients who need to make a decision to stop driving. DriveABLE is an Alberta-based company that provides objective and evidence-informed approaches to assessing driver ability, as well as resources for supporting individuals and families through this process.

Safe Kids Canada: <http://www.safekidscanada.ca/gateway.aspx>

Part of the national injury prevention program at Toronto's Hospital for Sick Children, Safe Kids Canada offers information on a range of safety topics to prevent accidental injuries in children.

SMARTRISK: <http://www.smartrisk.ca/>

SMARTRISK is a national nonprofit organization dedicated to preventing injuries and saving lives. Founded in 1992, SMARTRISK has become one of the leading injury-prevention groups in Canada and enjoys international recognition and support.

Hygiene

Original chapter by Deborah Marshall, MSN

Canadian content written by Yvonne G. Briggs, RN, BScN, MN

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Discuss common factors that influence personal hygiene practices.
- Discuss the role that the nursing process and critical thinking play in the provision of hygiene care.
- Conduct a comprehensive assessment of a patient's total hygiene needs.
- Understand the importance of foot care for the diabetic patient.
- Describe conditions that place the patient at risk for problems related to the hair, scalp, integument, feet, nails, eyes, ears, nose, mouth, and throat and discuss their related interventions.
- Describe how hygiene care for the older patient may differ from that for the younger patient.
- Discuss the different approaches used in maintaining a patient's comfort and safety during hygiene care.
- Successfully perform hygiene for care of the integument; perineum; feet, hands, and nails; mouth; and eyes, ears, and nose.

Personal hygiene affects an individual's comfort, safety, and physical and psychological well-being. Individuals who are well are capable of meeting their own hygiene needs, but those who are ill or have disabilities may require various levels of assistance. Many personal, social, and cultural factors can influence hygiene practices. In agency or home care settings, determine a patient's ability to perform self-care and provide hygiene care according to the patient's needs and preferences. In the home setting, assist in helping the patient and family to adapt hygiene techniques and approaches.

Because hygiene care requires close contact with the patient, therapeutic communication skills should be used (see Chapter 17) to build and promote a caring therapeutic relationship and to assist you in providing the patient with teaching regarding hygiene care. Other nursing activities can be integrated during hygiene care, including patient assessment and interventions, such as range-of-motion exercises, the application of dressings, and the inspection and care of intravenous (IV) sites. During hygiene care, the patient's independence is encouraged and promoted as much as possible, privacy is ensured, respect is conveyed, and physical comfort and safety is maintained and supported.

Scientific Knowledge Base

Proper hygiene care requires an understanding of the anatomy and physiology of the integument, oral cavity,

eyes, ears, nose, hands, feet, and nails. The skin and mucosal cells exchange oxygen, nutrients, and fluids with underlying blood vessels. The cells require adequate nutrition, hydration, and circulation to resist injury and disease. Good hygiene techniques assist in promoting the normal structure and function of body tissues.

In addition, knowledge of pathophysiology is applied to provide skilled preventive hygiene care. Learn to recognize disease states that create changes in the integument, oral cavity, and sensory organs. For example, diabetes mellitus results in chronic vascular changes that impair healing of the skin and mucosa. In the early stages of acquired immune deficiency syndrome (AIDS), fungal infections of the oral cavity are common. Stroke can result in paralysis of the trigeminal nerve, which eliminates the blink reflex, increasing the risk for corneal drying. In the presence of conditions such as these, hygiene practices are adapted to anticipate patient needs and minimize harmful effects. By integrating knowledge of anatomy, physiology, and pathophysiology during hygiene care, you can recognize abnormalities and initiate appropriate actions to prevent further injury.

The Skin

The skin is an active organ with the functions of protection, secretion, excretion, temperature regulation, and sensation (Table 37-1). The skin has three primary layers: epidermis,

dermis, and subcutaneous (see Chapter 31). Bacteria commonly reside on the outer layer (the **epidermis**). These resident bacteria are normal flora (see Chapter 32); they do not cause disease but instead inhibit the multiplication of disease-causing microorganisms.

The skin can provide crucial information regarding a patient's health status and provide important information regarding the functioning of other systems and organs (see Chapter 31).

The Feet, Hands, and Nails

The feet, hands, and nails often require special attention to prevent infection. Any injury or deformity to the foot, including growths or injuries to the overlying skin and nails, can be painful and thus interfere with a patient's normal ability to walk and weight-bear.

The hand, in contrast to the foot, is constructed largely for manipulation rather than support. Dexterity exists in the hand because of the wide range of movement between the thumb and fingers. Any condition that interferes with the movement of the hand (e.g., superficial or deep pain or joint inflammation) can impair a patient's self-care abilities.

The nails are epithelial tissues that grow from the root of the nail bed, which is located in the skin at the nail groove and hidden by the fold of skin called the **cuticle**. The visible part of the nail is the nail body. It has a crescent-shaped white area

► **TABLE 37-1** Function of the Skin and Implications for Care

Function and Description	Implications for Care
Protection The epidermis is relatively impermeable and protects the body from environmental stress (e.g. trauma, pathogens) and environmental factors (e.g. heat, cold).	Weakening of the epidermis occurs by scraping or stripping its surface (e.g., through the use of dry razors, tape removal, or improper turning or positioning techniques). Excessive dryness causes cracks and breaks in the skin and mucosa that allow bacteria to enter. Emollients soften the skin and prevent moisture loss, and hydration of the mucosa prevents dryness. Constant exposure of skin to moisture can cause maceration (softening), which interrupts dermal integrity and promotes ulcer formation and bacterial growth. Bed linen and clothing should be kept dry. Misuse of soaps, detergents, cosmetics, and deodorants can cause chemical irritation. Alkaline soaps neutralize the protective acid condition of skin. Cleansing of skin removes excess oil, sweat, dead skin cells, and dirt that can promote bacterial growth. Bath water should not be excessively hot or cold.
Sensation The skin contains sensory organs for touch, pain, temperature, and pressure.	Friction should be minimized to avoid the loss of the stratum corneum, which can result in the development of pressure ulcers. Smoothing linen removes sources of mechanical irritation. To prevent accidental injury of the patient's skin, nurses should remove their own jewellery before giving care.
Temperature Regulation Body temperature is controlled by evaporation of perspiration, radiation, and conduction of heat from the body when blood vessels of the skin are vasodilated through lack of perspiration and vasoconstriction.	Factors that interfere with heat loss can alter temperature control. Wet bed linens or gowns interfere with convection, conduction, and evaporation. Excess blankets or bed coverings can interfere with heat loss through radiation and conduction and promote heat conservation.
Absorption and Secretion The skin allows limited excretion of some metabolic wastes and by-products such as minerals, sugars, and uric acid. Sebum lubricates and softens the skin and hair and decreases the amount of heat loss from the skin.	Perspiration and oil can harbour microorganisms. Bathing removes excess body secretions; however, excessive bathing can cause drying of the skin.

Figure 37-1 Anatomical structure of a normal nail. **Source:** From McFarland, G. K., Hirsch, J. E., Tucker, S. M., & Thompson, J. M. (Eds.). (1997). *Mosby's clinical nursing* (4th ed.). St Louis, MO: Mosby.

known as the **lunula**. Under the nail lies a layer of epithelium called the nail bed (Figure 37-1). In light-skinned individuals, a healthy nail is transparent, smooth, and convex, with a pink nail bed and translucent white tip. Some disease processes can cause changes in the shape, thickness, and curvature of the nail (see Chapter 31).

The Oral Cavity

The oral cavity extends from the lips to the anterior pillars of the tonsils. It is the structure for taste, **mastication**, and speech articulation. The **buccal mucosa** (oral mucosa) are normally light pink and moist. The floor of the mouth and the under-surface of the tongue are richly supplied with blood vessels, which allows for rapid absorption of sublingual medications (e.g., nitroglycerin). Any type of ulceration or trauma to the area can result in significant bleeding. The mouth also contains three pairs of salivary glands that start the digestive process by releasing enzymes, protect the mucosa from heat and chemical irritants, transmit taste information, and provide lubrication for the movement of food. Salivary secretion can be decreased by medications and disease processes.

There are 32 permanent teeth for chewing, or mastication. They are designed to cut, tear, and grind food so that it can be mixed with saliva and swallowed. A normal tooth consists of a crown, neck, and root (Figure 37-2). The periodontal membrane lies just below the gum margins, surrounds a tooth, and holds it firmly in place. Healthy teeth are free from cavities and are properly aligned.

Difficulty with chewing can develop when gum tissues become inflamed or infected or when teeth are lost or become loose. Regular oral hygiene is necessary to maintain the integrity of tooth surfaces and to prevent **gingivitis** (gum inflammation) and **periodontal disease**.

The Hair

Hair is produced by hair follicles located in the **dermis** (Figure 37-3). Hair growth, distribution, and pattern can indicate a person's general health status. Hormonal changes, emotional and physical stresses, aging, infection, and certain illnesses can affect hair colour and condition. The hair shaft itself is inert and cannot be directly affected by physiological factors. However, changes in its colour or condition are caused by hormonal or nutrient deficiencies of the hair follicle (see Figure 37-3).

Figure 37-2 A normal tooth.

Figure 37-3 Hair follicles and relationship of follicles and their related structures to the epidermal and dermal layers of the skin. **Source:** From Lewis, S. M., Heitkemper, M. M., Dirksen, R. R., et al. (2007). *Medical-surgical nursing: Assessment and management of clinical problems* (7th ed., p. 450, Fig. 23-1). St Louis, MO: Mosby.

The Eyes, Ears, and Nose

The eyes, ears, and nose require careful attention during the provision of hygiene. Chapter 31 describes the structure and function of these organs. Cleansing of these sensitive sensory tissues should be done in a way that prevents injury and discomfort for the patient, such as being careful not to get soap in the patient's eyes. In addition, the time that is spent with a patient during hygiene provides an excellent opportunity to ask whether he or she has experienced any changes in vision, hearing, or sense of smell.

Nursing Knowledge Base

Hygiene care is never routine; the care requires intimate contact with patients, and good communication skills are necessary to build and promote a therapeutic relationship. No two

individuals perform hygiene in the same manner, and it is important to individualize care from knowledge about the patient's unique hygiene practices and preferences.

While providing hygiene care, you can learn about patients' health promotion practices and needs, emotional needs, and needs pertaining to health care education. A patient's personal preferences for hygiene can be influenced by a number of factors.

Social Practices

Social groups influence hygiene preferences and practices, including the type of hygiene products used and the nature and frequency of personal care. During childhood, hygiene is influenced by family customs, including, for example, the frequency of bathing, the time of day bathing is performed, and the type of oral hygiene practised. As children enter their adolescent years, personal hygiene may be influenced by peer group behaviour, and they may become more interested in their personal appearance. For example, girls may begin to wear makeup, and boys may begin shaving. During the adult years, involvement with friends and work groups shapes the expectations individuals have about their personal appearance. Older adults' hygiene practices may change because of living conditions, health status, and available resources.

Personal Preferences

Each patient has individual preferences about when to bathe, shave, and perform hair care. Patients select different products according to personal preferences and needs. These preferences should assist you in delivering individualized care for patients. In addition, you should assist patients in developing new hygiene practices when necessitated by an illness or condition.

Body Image

Patients' general appearance may reflect the importance that hygiene holds for them. Body image is a person's subjective concept of his or her physical appearance (see Chapter 25), and it can change frequently. When patients undergo surgery, illness, or a change in physical or mental health status, body image can alter dramatically. For this reason, effort should be taken to promote patients' hygienic comfort and appearance.

Body image affects the way in which hygiene is maintained. If patients are neatly groomed, you should consider the details of grooming when planning care and consult with the patients before making decisions about how hygiene care is to be provided. Patients who appear unkempt or uninterested in hygiene may require an assessment of their hygiene practices or additional education about the importance of hygiene.

Socioeconomic Status

A person's economic resources can influence the type and extent of hygiene practices used. You should be sensitive in considering whether a patient's economic status influences his or her ability to regularly maintain hygiene. When patients have the added problem of a lack of resources, it becomes difficult to participate and take a responsible role in health promotion activities such as basic hygiene.

When basic care items are not affordable, alternatives need to be considered. It is also important to assess whether the use of these products is an acceptable practice among patients' social or cultural group. For example, not all patients may choose to use deodorant or cosmetics.

Health Beliefs and Motivation

Knowledge about the importance of hygiene and its implications for well-being influences hygiene practices. However, knowledge alone is not enough. According to Pender et al. (2006), individual characteristics such as personal factors (psychological, sociocultural, and biological) directly influence an individual's health promotion activities.

It is important to know, for example, whether patients perceive that they are at risk for dental disease, that dental disease is serious, and that brushing and flossing are effective in reducing this risk. When patients recognize that a risk is present and that reasonable action can be taken to reduce the risk, they are more receptive to counselling and teaching efforts.

Cultural Variables

Patients' cultural beliefs and personal values can influence hygiene care (Box 37-1). Individuals from diverse cultural backgrounds follow different self-care practices (see Chapter 9). Feelings of disapproval must not be conveyed when caring for patients whose hygienic practices are different from your own. In some cultures, it is customary to bathe once a week; in North America, it is common to bathe or shower daily.

Physical Condition

Patients with certain types of physical limitations, disabilities, or pain often lack the physical energy, dexterity, and range of

► BOX 37-1 Cultural Influences on Hygiene

Patients need a culturally competent plan for hygiene care. For some, hygiene practices are influenced by culture and are a potential source of conflict and stress in a hospital environment. Hygiene is a very personal matter and bathing, perineal hygiene, and hair care practices can be sensitive issues. Using knowledge from theoretical models allows the health care provider to provide culturally sensitive care that respects and incorporates the patient's cultural background.

Implications for Practice

- Maintain privacy, especially for women from cultures that value female modesty.
- Be aware that in some cultures, touch has many different meanings: touching the shoulder of a Japanese man can cause feelings of humiliation; Asian women do not shake hands with other women or men; for some Aboriginal people, touch can mean a prevention of harm.
- Be aware that silence, to the patient of Asian descent, can be interpreted as a sign of respect.
- Provide gender-congruent caregivers as needed or requested. If a gender-congruent caregiver is not available, ask the family for assistance.
- Do not cut or shave a patient's hair without prior discussion with the patient or family.
- Be aware that some cultures (e.g., Chinese, Filipino) discourage bathing for 7 to 10 days after childbirth.
- Bear in mind that some cultures (e.g., Chinese, Japanese, Korean, Hindu) consider the top parts of the body cleaner than the lower parts.
- Be aware that among Hindus and Muslims, the left hand is used for cleaning and the right hand is used for eating and praying.

Data from Galanti, G. A. (2008). *Caring for patients from different cultures* (4th ed.). Philadelphia, PA: University of Pennsylvania; and Giger, J., & Davidhizar, R. E. (2008). *Transcultural nursing: Assessment and intervention* (5th ed.). St Louis, MO: Mosby Elsevier.

motion to perform hygiene care. A patient in traction or a cast or who has an IV line or other device connected to the body needs assistance with hygiene. Patients under the effects of sedation do not have the mental clarity or coordination to perform self-care. Chronic illnesses, such as cardiac disease, cancer, neurological disorders, and certain psychiatric conditions, may exhaust or incapacitate a patient. A weakened grasp resulting from arthritis, stroke, or muscular disorders can prevent a patient from using a toothbrush, washcloth, or comb.

Critical Thinking

Successful critical thinking requires the synthesis of knowledge, experience, information gathered from patients, critical thinking qualities, and intellectual and professional standards. Clinical judgements require you to anticipate the information necessary to analyze data and make decisions regarding patient care. Patients' conditions are always changing, requiring ongoing critical thinking. During assessment, you must consider all contributing factors needed to make a nursing diagnosis (Figure 37-4).

Because hygiene care is so important for patients to feel comfortable, refreshed, and renewed, you should avoid

making hygiene care a simple routine. Instead, integrate knowledge from nursing and other disciplines, previous experiences, and information gathered from patients. In addition, use attributes such as curiosity and humility when designing a plan of care that will meet the patients' hygiene needs. Agency and professional nursing standards and guidelines, such as those from the Registered Nurses' Association of Ontario (RNAO), are used when planning care to meet the patient's hygiene needs.

Nursing Process

❖ Assessment

Important considerations include assessment of the patient's ability to perform self-care, usual hygiene practices, and preferences with special attention to balance, coordination, strength, range of motion, and activity tolerance. Nursing assessment is an ongoing process. It involves all phases of the nursing process, including goal setting, planning, intervention, and evaluation. Not all body regions need to be assessed before administering hygiene; however, routine assessment of a patient's condition is undertaken whenever patient care is provided. For example, during oral care, the condition of the teeth and mucosa can be inspected. If the patient has had a repeated problem (e.g., dry skin or inflamed oral mucosa), then it is important to conduct an assessment before care is administered because variations in technique may be necessary.

Physical Examination

While assisting a patient with personal hygiene, carefully assess the integument, oral cavity structures, and the eyes, ears, and nose (see Chapter 31). Using the skills of inspection and palpation, look for alterations in the integrity and function of tissues. Your assessment also reveals the type and extent of hygiene care required and the need for specialized equipment (e.g. grab bars, tub chair). Special attention should be given to the structures most influenced by hygiene measures. Is the skin intact, especially over bony prominences? Is the skin dry from too much bathing? Are calluses present on the feet, which may benefit from soaking? Is a coating of the tongue present, which necessitates frequent oral care? Over time, your assessment provides the baseline for determining whether hygienic measures maintain or improve the patient's condition.

The Skin. While inspecting the skin, thoroughly examine its colour, texture, thickness, turgor, temperature, and hydration. The skin should be smooth, warm, and supple and have good turgor. Pay special attention to the presence and condition of any lesions (see Chapter 31), and assess for dryness indicated by flaking, redness, scaling, and cracking. Certain common skin problems affect how hygiene is administered (Table 37-2). Assess tattoos and body piercings for potential health risks such as skin irritation and infection, which are the most prevalent associated complications (Deschesnes et al., 2006). Serious complications such as hepatitis B or C, or HIV/AIDS, or even death, can also result from body piercings and tattoos (Hayward & Tindale, 2008). Careful attention should be paid in assessing less obvious or difficult-to-reach skin surfaces, such as under the female patient's breasts, under the male patient's scrotum, or around the female's perineal tissues. Observed skin problems should be documented, explained to the patient, and teaching on proper skin care and specific hygiene techniques should also be discussed with the patient.

Figure 37-4 Critical thinking model for hygiene assessment. AHCPR, Agency for Health Care Policy and Research; RNAO, Registered Nurses Association of Ontario.

► TABLE 37-2 Common Skin Problems

Characteristics	Implications	Interventions
Dry Skin Flaky, rough texture on exposed areas such as hands, arms, legs, or face	Skin may become infected if epidermal layer is allowed to crack.	Bathing should be less frequent and the skin rinsed of all soap residue, because if left on the skin, soap can cause irritation and skin breakdown. Increase/encourage fluid intake, if permitted. Use a nonallergenic moisturizing cream—to help form a protective barrier and assist with keeping fluid within the skin. Use creams to clean skin that is dry or if patient is allergic to soaps or detergents.
Acne Inflammatory, papulopustular skin eruption, usually involving bacterial breakdown of sebum; appears on face, neck, shoulders, and back	Infected material within pustule can spread if area is squeezed or picked. Permanent scarring can result.	Wash hair and skin thoroughly each day with soap to remove excess oil and prevent secondary infections. Use cosmetics sparingly, as oily cosmetics and creams accumulate in pores and tend to worsen the condition. Use prescribed topical or oral antibiotics.
Skin Rashes Skin eruption that may result from overexposure to sun or moisture or from an allergic reaction (may be flat or raised, localized or systemic, pruritic or nonpruritic)	If skin is continually scratched, inflammation and infection may occur.	Wash the area thoroughly and apply an antiseptic spray or lotion to prevent further itching and aid in the healing process. Apply warm or cold compresses to relieve inflammation, if indicated.
Contact Dermatitis Inflammation of skin characterized by abrupt onset with erythema, pruritus, pain, and appearance of scaly oozing lesions (seen on face, neck, hands, forearms, and genitalia)	Dermatitis is often difficult to eliminate because the person is usually in continual contact with the substance causing the skin reaction, and it may be hard to identify this substance.	Avoid causative agents (e.g., cleansers and soaps).
Psoriasis Noncontagious, chronic skin condition characterized by an abnormal growth of keratinocytes (a type of skin cell) and an inflammatory reaction that results in the formation of thick, silvery, scaly, inflamed patches of skin; commonly seen on the scalp, knees, elbows, and chest	The cause of psoriasis is unknown, and no cure exists. It is often difficult to diagnosis as it has similar symptoms to eczema and atopic dermatitis.	Treatment options are aimed at reducing the extent and severity of the condition and improving quality of life. The patient should avoid trigger agents such as smoking, stress, excessive alcohol, and skin injury (e.g., sunburn).
Abrasion Scraping or rubbing away of epidermis that may result in localized bleeding and later weeping of serous fluid	Infection occurs easily because of the loss of this protective skin layer.	Trim your fingernails and do not wear jewellery when providing patient care. Cleanse area and dry thoroughly and gently. Observe for retained moisture in dressings or bandages—excess moisture can increase the risk of infection. Lift—do not pull—when transferring or repositioning a patient (see Chapter 45).

► BOX 37-2 Risk Factors for Skin Impairment

Immobilization

When restricted from moving freely, patients' dependent body parts are exposed to pressure, reducing circulation to the affected body parts. You should know which patients require assistance to turn and reposition.

Reduced Sensation

Patients with paralysis, circulatory insufficiency, or local nerve damage are unable to sense an injury to the skin. While bathing a patient, assess the status of sensory nerve function by checking for pain, tactile sensation, and temperature sensation.

Nutrition and Hydration Alterations

Patients with limited caloric and protein intake can develop thinner, less elastic skin, with a loss of subcutaneous tissue. This can result in impaired delayed wound healing.

Secretions and Excretions on the Skin

Moisture on the skin's surface serves as a medium for bacterial growth and can cause irritation, soften epidermal cells, and lead to skin breakdown. The presence of perspiration, urine, fecal material, or wound drainage on the skin can also result in breakdown or infection, or both.

Vascular Insufficiency

Inadequate arterial supply to tissues and impaired venous return decrease the circulation to the extremities. Inadequate blood flow can cause ischemia and tissue breakdown. The risk of infection also exists because the delivery of nutrients, oxygen, and white blood cells to injured tissues is inadequate.

External Devices

An external device applied to or around the skin exerts pressure and friction on the skin. Assess all surfaces exposed to casts, cloth restraints, bandages and dressings, tubing, or orthopedic braces.

Certain conditions place patients at risk for impaired skin integrity (Box 37-2). You must be particularly alert when assessing patients with reduced sensation, vascular insufficiency, or immobility. Make sure to assess both extremities and assist patients in turning so that skin surfaces can be fully viewed. The development of pressure ulcers is a common complication that can extend hospital stays and threaten the well-being of long-term care patients. Tools such as the Braden Scale (Gulanick & Myers, 2007) are available to determine those patients who may be at risk for impaired skin integrity. When caring for patients with darkly pigmented skin, you should be aware of assessment techniques and skin characteristics unique to highly pigmented skin (Box 37-3).

The Feet and Nails. When assessing the feet, perform a thorough examination of all skin surfaces, including the areas between the toes and over the soles of the feet. The heels, soles, sides of the feet, and "knuckles" of the toes are prone to irritation from poorly fitting shoes. In addition, inspect the shape and size of the toes, as well as the shape of the foot. The toes are normally straight and flat. The feet should be in straight alignment with the ankle and tibia. Inspect the feet for lesions and note areas of dryness, inflammation, or cracking.

Assess the patient's gait. Painful foot disorders or decreased sensation can cause limping or an unnatural gait. Inquire whether the patient has foot discomfort and determine factors that aggravate the pain. Foot problems may result from bone

► BOX 37-3 Skin Assessment and Implications for Practice

Identifying changes in skin colour is important in evaluating patients' risks for skin breakdown and pressure ulcers (see Chapter 46). When a patient's natural skin contains more melanin, it is more difficult to determine hyperemia and cyanosis. Some hyperpigmentation areas are normal, such as Mongolian spots, which may be on the sacrum of African, Aboriginal, and Asian patients. These areas should not be confused with skin colour changes such as hyperemia or cyanosis.

Implications for Practice

For dark-skinned patients, assess baseline skin tone by asking the patient or family to point out an area of baseline skin colour for that person. Assess the oral mucosa, over the cheekbones, and conjunctivae in the dark-skinned patient, and the nail beds and lips in light-skinned patients.

Assess localized skin changes:

- Colour darker than surrounding skin colour; purplish, bluish (cyanosis), eggplant
- Taut skin
- Shiny skin
- Induration (hardening of the tissues)
- Use natural light sources when possible because fluorescent light can give the skin a bluish tone
- Examine the body sites with the least amount of melanin for underlying skin colour identification.

Assess for edema (non-pitting, pitting) (see Chapter 31)

Assess skin temperature, using the back of your hand; if the patient's condition permits, do not use gloves when doing this assessment:

- Initially may feel warmer than surrounding skin
- Subsequently may feel cooler than surrounding skin

Data from Estes, M. E., & Buck, M. (2008). *Health assessment and physical assessment* (1st Cdn. ed.). Toronto: Thomson Nelson; MacDonald-Jenkins, J. (2009b). Skin, hair, and nails. In C. Jarvis, A. Browne, J. MacDonald-Jenkins, and M. Luctkar-Flude (Eds.), *Physical examination and health assessment* (1st Canadian ed., pp. 295, 315). Toronto: Elsevier Canada; and Stephen, T. C. (2010). Assessment of integumentary function. In R. A. Day, P. Paul, B. Williams, S. C. Smeltzer, and B. G. Bare (Eds.), *Brunner & Suddarth's textbook of Canadian medical-surgical nursing* (2nd ed.) (pp. 1818–1835). Philadelphia, PA: Lippincott Williams & Wilkins.

or muscular alterations or wearing poor-fitting footwear, rather than skin disorders.

Patients with peripheral vascular disease, diabetes mellitus, and other diseases that affect peripheral circulation and sensation should be assessed for the adequacy of circulation to the feet (see Chapter 31). Inspection and daily foot care can help prevent the development of a foot ulcer. Foot ulcerations are a predisposing factor for lower extremity amputations in individuals with diabetes mellitus (Ogrin & McLaren, 2010).

Palpation of the dorsalis pedis and posterior tibial pulses indicates whether adequate blood flow is reaching peripheral tissues. Edema and changes in skin colour, texture, and temperature can indicate whether patients require special hygiene care. Individuals with diabetes mellitus should also be assessed for **neuropathy**—degeneration of the peripheral nerves characterized by a loss of sensation. Assess patients' sensation to light touch, pain, and temperature.

Inspect the condition of the fingernails and toenails, looking for lesions, dryness, inflammation, and cracking (Table 37-3). The nail is surrounded by a cuticle, which slowly grows over the nail and must be regularly pushed back. The skin around

► **TABLE 37-3** Common Foot and Nail Problems

Characteristics	Implications	Interventions
Callus A thickened portion of the epidermis consisting of a mass of horny, keratotic cells. It is usually flat, painless, and found on the undersurface of the foot or on the palm of the hand. Caused by local friction or pressure.	The condition may cause discomfort when wearing tight shoes.	Advise the patient to wear gloves when using tools or objects that may create friction on palmar surfaces, and to wear soft-soled shoes with insoles. Soak callus in warm water and magnesium sulphate (Epsom salts) to soften the cell layers. Apply cream or lotion to reduce reformation. Encourage the patient to see a podiatrist (ensure that the patient is aware of the associated cost).
Keratoses (corn) Corns are caused by chronic friction and pressure from ill-fitting or loose shoes. It is seen mainly on or between toes or over a bony prominence. A corn is usually cone shaped, round, and raised. Soft corns are macerated.	The conical shape compresses the underlying dermis, making it thin and tender. The pain worsens when tight shoes are worn. Corns can become soft and macerated by perspiration. The patient may suffer an alteration in gait resulting from pain.	Surgical removal may be necessary, depending on the severity of pain and size of the corn. Avoid the use of oval corn pads, which can increase pressure on toes and reduce circulation. Use warm water soaks to soften the corns before gentle rubbing with a callus file or pumice stone (consult with physician or podiatrist). Wider and softer shoes are suggested.
Plantar Wart A fungating lesion caused by the papillomavirus that appears on the sole of foot.	Warts may be contagious, are painful, and can make walking difficult.	Treatment ordered may include applications of salicylic acid, electrodesiccation (burning with electrical spark), or freezing with solid carbon dioxide.
Athlete's Foot (Tinea Pedis) A fungal infection of the foot; scaliness and cracking of skin occurs between the toes and on the soles of feet. Small blisters containing fluid may appear. The problem can be caused by wearing constricting footwear.	Athlete's foot can spread to other body parts, especially the hands. It is contagious and frequently recurs.	Feet should be well ventilated. Drying feet well after bathing and applying powder helps to prevent infection. Wearing clean socks or stockings reduces the incidence. The physician or nurse practitioner may prescribe antifungal topical applications.
Ingrown Nail An ingrown toenail or fingernail grows inward into the soft tissue around nail. An ingrown nail often results from improper nail trimming.	Ingrown nails can cause localized pain when pressure is applied and can lead to infection.	Treatment is frequent hot soaks in an antiseptic solution and removal of the portion of nail that has grown into skin. Instruct the patient regarding proper nail-trimming techniques, and provide a referral to a podiatrist. (Ensure that the patient is aware of the associated cost.)
Ram's Horn Nail An unusually long, curved, thickened nail.	Attempts to cut ram's horn nails may result in damage to the nail bed with an increased risk of infection.	Refer the patient to a podiatrist. (Ensure that the patient is aware of the associated cost.)
Paronychia Inflammation of tissue surrounding the nail, after a hangnail or other injury. It occurs in individuals who frequently have their hands in water and is common in patients with diabetes.	Infection	Treatment can include hot compresses or soaks, or topical or oral antibiotics. Can be prevented by careful manicuring.
Foot Odour Results from excess perspiration, promoting microorganism growth.	The condition may cause discomfort because of excess perspiration and odour, and increases patients' risk for infection.	Frequent washing, using foot deodorants and powders, and wearing clean footwear prevents or reduces the problem.

the nail beds and cuticles should be smooth and without inflammation. You should ask women whether they frequently polish their nails and use polish remover because chemicals in these products can cause excessive nail dryness and discolouration. Disease can change the shape and curvature of the nails. Inflammatory lesions and fungus of the nail bed can cause thickened, horny nails, which can separate from the nail bed.

The Oral Cavity. Inspect all areas of the oral cavity carefully for colour, hydration, texture, and lesions (see Chapter 31). Patients who do not follow regular oral hygiene practices may have receding gum tissue, gingivitis, a coated tongue, discoloured teeth (particularly along the gum margins), dental caries, missing teeth, and **halitosis** (bad breath). Localized pain and infection are common symptoms of periodontal disease and certain tooth disorders.

Some patients in acute care settings require a complete oral assessment. The identification of risks for infection and other conditions can suggest the type and frequency of oral care. Proper oral care has been shown to decrease the risk of aspiration and nosocomial infections in ventilated patients (Mori et al., 2006). Ebersole et al. (2008) posit that Gram-negative bacteria (e.g., *Pseudomonas aeruginosa*) found in dental plaque can result in pneumonia in hospitalized older adults. It is especially important to examine the oral cavity of patients receiving radiation or chemotherapy. Both treatments can reduce the amount of saliva, resulting in drying and **stomatitis** (inflammation of the oral mucosal tissues). The assessment serves as a basis for preventive care for patients as they undergo treatment.

The Hair. Before performing hair care, assess the condition of the hair and scalp. Healthy hair is clean, shiny, and untangled; the scalp is free of lesions. The hair of dark-skinned patients is usually thicker, drier, and curlier than that of lighter-skinned patients. Table 37-4 summarizes hair and scalp problems that may be identified during the assessment. In community and home care settings, it is particularly important to inspect the hair for pediculosis capitis (head lice) so that the appropriate treatment can be provided. If head lice are suspected, guard against self-infestations by handwashing and using gloves or tongue blades to inspect the patient's hair. A loss of hair (**alopecia**) can result from the effects of chemotherapy medications, hormonal changes, or improper hair care practices. Patients at risk for scalp problems are those who have experienced head trauma and those who practise poor hygiene.

The Eyes, Ears, and Nose. Examine the condition and function of the eyes, ears, and nose (see Chapter 31). Normally the eyes are free of infection and irritation. The sclerae are visible anteriorly as the white portion of the eye. The conjunctivae (the lining of the eyelids) are clear, pink, and without inflammation. The eyelid margins are in close approximation with the eyeball, and the lashes are turned outward. The lid margins are without inflammation, drainage, or lesions. The eyebrows are symmetrical.

Determine whether the patient wears contact lenses. This is especially significant for patients who enter hospitals or other agencies unresponsive or in a confused state. To determine whether a contact lens is present, stand to the side of the patient's eye and observe the cornea for the presence of a soft or rigid lens; if you do not see one, observe the sclera to detect whether a contact lens has shifted off the patient's cornea. An undetected lens can cause severe corneal injury if left in place too long.

Inspect the external ear structures (auricle, helix, and earlobe), and use an otoscope to inspect the external auditory canal and tympanic membrane. While performing hygiene measures, you are most concerned with noting the presence of accumulated **cerumen** or drainage in the ear canal, local inflammation, tenderness on palpation, or the patient's report of pain (see Chapter 31).

Inspect the nares for signs of inflammation, discharge, lesions, edema, and deformity (see Chapter 31). The nasal mucosa is normally pink and clear and has little or no discharge. A clear, watery discharge may be the result of allergies. If patients have any form of tubing exiting the nose (e.g., nasogastric tube), inspect the naris surfaces that come in contact with the tubing for tissue sloughing, localized tenderness, inflammation, and bleeding.

Developmental Changes

The normal process of aging influences the condition of body tissues and structures and, thus, the manner in which hygiene measures are performed. Chapter 47 addresses the changes in hearing, vision, and olfaction across the lifespan as a result of growth and development.

The Skin. Neonates' skin is relatively immature at birth. The epidermis and dermis are loosely bound together, and the skin is very thin. Friction against the skin layers can cause bruising, so neonates must be handled carefully during bathing. Any break in the skin can easily lead to infection.

Toddlers' skin layers are more tightly bound together. Thus, children have a greater resistance to infection and skin irritation. However, because of children's active play and the absence of established hygiene habits, greater attention is needed from parents and caregivers to provide thorough hygiene and to begin teaching good hygiene habits.

During adolescence, the growth and maturation of the integument increases. In girls, estrogen secretion causes the skin to become soft, smooth, and thicker, with increased vascularity. In boys, male hormones produce an increased thickness of the skin with some darkening in colour. Sebaceous glands become more active, predisposing adolescents to **acne**. Eccrine and apocrine sweat glands become fully functional during puberty. Adolescents usually begin to use deodorants, and more frequent bathing and shampooing become necessary to reduce body odours and eliminate oily hair. Sweating is usually more pronounced in boys.

The condition of adults' skin depends on hygiene practices and exposure to environmental irritants. Normally, the skin is elastic, well hydrated, firm, and smooth. When adults practise frequent bathing or are exposed to an environment with low humidity, the skin can become very dry and flaky.

With aging, the skin loses its resiliency and moisture, and sebaceous and sweat glands become less active. The epithelium thins, and elastic collagen fibres shrink, making the skin fragile and subject to bruising and breaking. These changes warrant caution when turning and repositioning older adults (Meiner & Lueckenotte, 2006). Typically, older adults' skin becomes drier and wrinkled. Because the skin may be excessively dry, older adults should avoid bathing daily and using very hot water or harsh soaps.

The Feet and Nails. When we stand, the feet provide support and absorb shock. With aging, they begin to show signs of wear and tear. This may occur earlier if individuals have failed to wear comfortable, supportive footwear. The cushioning layer of fat on the soles of the feet becomes thin.

► **TABLE 37-4** Problems of Head and Body Hair and Scalp

Characteristics	Implications	Interventions
Dandruff Scaling of the scalp is accompanied by itching. In severe cases, dandruff can be found on eyebrows.	Dandruff causes individuals embarrassment and if it enters the eyes, conjunctivitis may develop.	Shampoo regularly with a medicated shampoo. In severe cases, obtain a physician's advice.
Ticks Small, grey-brown parasites that burrow into the skin and suck the blood.	Ticks transmit several diseases to individuals. The most common are Rocky Mountain spotted fever, tularemia, and Lyme disease.	Do not pull ticks quickly from the skin because their sucking apparatus remains and may cause infection. Ticks can be removed slowly with tweezers.
Pediculosis Capitis (Head Lice) Head lice require a source of human blood to survive. Transmission is by direct contact (e.g., head to head). The parasite is found near the scalp attached to hair strands. Eggs look like oval particles, similar to dandruff. Bites or pustules may be observed behind the ears and at the hairline. Itching at the hairline is the most common symptom.	Contacts of the patients (e.g., family members and classmates) should be examined and treated. Although no current evidence exists of transmission by shared articles, families may wish to wash bedding and combs in hot water. Dry-cleaning or storing items in occlusive plastic bags for approximately two weeks is also effective (Canadian Paediatric Society [CPS], 2008).	Check the entire scalp. Use a medicated shampoo to eliminate lice. Follow the product directions carefully; a repeat application is required 7–10 days later to ensure that surviving eggs are destroyed. Seek physician advice if treatment is ineffective; a new medication may be required for effective chemical eradication. Some products can cause neurotoxicity and should not be used with children under six years of age. Caution is advised against use of products containing lindane. This product has been withdrawn for use in some countries. Use a fine-toothed comb to assist with the manual removal of nits (the empty eggshell) and lice.
Pediculosis Corporis (Body Lice) Body lice differ from head lice in that they tend to cling to clothing and may not be easily seen. They suck blood and lay eggs on clothing and furniture.	The patient itches constantly. Scratches seen on the skin may become infected. Hemorrhagic spots may appear on skin where lice are sucking blood.	Ask the patient to bathe or shower thoroughly. After the skin is dried, apply a recommended pediculicide lotion. After 8–12 hours, have the patient take another bath or shower. Bag infested clothing or linen until laundered in hot water. Vacuum rooms thoroughly and throw away the bag after completion.
Pediculosis Pubis (Crab Lice) Crab lice parasites are found in pubic hair. Crab lice are greyish white with red legs.	Lice may be spread via bed linen, clothing, furniture, or via sexual contact.	Cleanse as for body lice. Treatment of sexual partners is recommended.
Hair Loss (Alopecia) Alopecia occurs in individuals of all races. Balding patches are seen at the periphery of the hairline. Hair becomes brittle and broken. The condition can be caused by genetics, the use of hair curlers or hair picks, tight braiding, and some medications.	Patches of uneven hair growth and loss alter the patient's appearance and affect self-image.	Advise the patient to stop any hair care practices that might be further damaging the hair.

Chronic foot problems are a common result of poor foot care, improperly fitting footwear, aging, and systemic disease. Older adults often have dry feet because of a decrease in sebaceous gland secretion, dehydration of epidermal cells, and poor condition of footwear. Callus formation and decreased sensation place the patient at a high risk for the development of foot ulcers (Senthuran, 2010). Painful feet can be the result of congenital deformities, weak structure, injuries, and diseases

such as diabetes, rheumatoid arthritis, or osteoarthritis. After 55 years of age, arthritis is a common cause of changes in the feet. Additional common foot problems are hammer toes, hallux valgus (bunions), corns, and ingrown toenails (Senthuran, 2010).

Fungal infections can occur under toenails, causing dark yellow streaks or total discolouration. The nails can also become opaque, scaly, and hypertrophied. If foot or nail

problems stay unresolved, patients can easily become disabled. You must apply knowledge of typical changes in the feet and nails when anticipating the type of hygiene that patients will require.

The Oral Cavity. Infants begin teething at approximately six to eight months of age (Wilson, 2007). The first permanent (secondary) teeth erupt at about six years of age. From adolescence, when all of the permanent teeth are in place, through middle adulthood, the teeth and gums remain healthy if individuals avoid fermentable carbohydrates and sticky sweets. Regular dental care and hygiene practices such as brushing and flossing help to prevent caries and periodontal disease.

As individuals grow older, numerous factors can result in poor oral care. These include age-related changes of the mouth, chronic disease such as diabetes, physical disabilities involving hand grasp or strength affecting the ability to perform oral care, lack of attention to oral care, and prescribed medications that affect the buccal (oral) mucosa. Aging teeth become brittle, drier, and darker. Teeth can become uneven, jagged, and fractured. Gums lose vascularity and tissue elasticity, which can cause dentures to fit poorly. Many older adults are edentulous and wear complete or partial dentures. It is important to determine whether older patients wear dentures and the condition of underlying supportive gum tissue.

The Eyes, Ears, and Nose. Although the structure of the eyes does not have marked developmental changes, altered visual acuity can occur at several points during the aging process; for example, when children start school or when patients reach middle age, visual acuity may change. As patients age, they are also at risk for changes in visual clarity (e.g., caused by glaucoma or cataracts) and visual field losses (e.g., caused by macular degeneration or glaucoma).

Structures of the ears do not change as patients age; however, changes in hearing acuity or balance may occur with aging. In young children, changes in hearing acuity may result from a foreign object being placed in the ear—this may be a temporary change, resolved once the object is removed. Changes may also result from repeated ear infections or exposure to loud noise, such as when children listen to loud music on headphones.

Older adults may have changes in the structure and function of the small bones in the inner ear that affect hearing acuity. Aging may result in increased cerumen production, which can also impede hearing acuity. In addition, the movement of fluid through the semicircular canals may change with age, and patients may experience positional dizziness or balance problems.

Although changes in the sense of smell can occur at any time, they seem to be more common in older adults. These changes may also affect taste and patients' appetite.

New and acute changes in the structure and function of the eyes, ears, and nose must be fully assessed and evaluated. Timely evaluation of these changes may confirm that they are age related or identify other illnesses.

Use of Sensory Aids

When patients wear eyeglasses, contact lenses, artificial eyes, or hearing aids, assess their knowledge and ask them to describe the methods that are used for routine care (Box 37-4). Compare the information gathered with the proper care technique for these devices. Any differences between patient practice and standard practice may indicate a need for patient education.

► BOX 37-4

Assessing a Patient's Use of Sensory Aids

Eyeglasses

- Ask about purpose for wearing glasses (e.g., reading, distance, or both)
- Ask about methods used to clean glasses
- Ask about presence of symptoms (e.g., blurred vision, photophobia, headaches, irritation)

Contact Lenses

- Determine type of lens worn
- Ask about frequency and duration of time lenses are worn (including sleep time)
- Ask about presence of symptoms (e.g., burning, excess tearing, redness, irritation, swelling, or sensitivity to light)
- Ask about techniques used by the patient to cleanse, store, insert, and remove lenses
- Ask about use of eye drops or ointments
- Determine whether patient has an emergency identification bracelet or card that alerts others to remove patient's lenses in case of emergency

Artificial Eye

- Ask about method used to insert and remove eye
- Ask about method for cleansing eye
- Ask about presence of symptoms (e.g., drainage, inflammation, or pain involving the orbit)

Hearing Aid

- Ask about type of aid worn
- Ask about methods used to cleanse aid
- Ask about patient's ability to change battery and adjust hearing aid volume

Self-Care Ability

Patients with physical or cognitive impairments need assistance with all or some aspects of personal hygiene. Assessment of patients' physical and cognitive statuses determines specifically which aspects of hygiene care can be performed independently, which require some assistance, and which require total assistance.

The assessment must include the measurement of patients' muscle strength, flexibility and dexterity, balance, coordination, and activity tolerance—these qualities are needed to perform activities such as bathing, brushing teeth, and bending over to inspect the feet. The degree of assistance needed by patients during hygiene care may also depend on vision, their ability to sit without support, their hand grasp strength, the range of motion in their extremities, or the presence of equipment such as an IV line, dressings, or traction. Painful conditions of the upper extremities pose special problems. Assess self-care ability by asking patients to perform activities such as brushing their teeth or combing their hair. Observe them carefully and note whether the patients can perform the task thoroughly and correctly (Figure 37-5).

When a patient has self-care limitations, part of the assessment is to determine whether family or friends are available to assist. Assisting with hygiene measures can at times be unpleasant, so the assessment should include how the family members assist, how often this assistance is provided, and what their feelings are about being a caregiver. In addition,

Figure 37-5 Observe the patient brushing teeth. Observation allows you to determine how much assistance the patient may need.

assess the home environment and its influence on the patient's hygiene practices. Does the home environment contain barriers that may affect the patient's self-care abilities? Water faucets that are too tight to easily adjust, bathtubs with high sides, and a bathroom too small to fit a wheelchair or walker in front of a sink are a few examples.

Hygiene Practices

An assessment of hygiene practices reveals a patient's grooming preferences. For example, a patient may choose to groom the hair in a certain style or to trim nails a certain way. When a patient has a physical disability, special precautions may be needed to perform grooming without injury. Asking the patient to assist or teach how to perform preferred grooming practices gives the patient a greater sense of independence and helps you to avoid causing the patient discomfort or injury.

Cultural Factors

A patient's cultural background is an influential factor when determining hygiene needs. Culture plays a role not only in hygiene practices and preferences but also in sensitivity regarding personal space (see Chapter 9). For example, some patients may view tasks associated with closeness and touch as being offensive or impolite. Ask patients what would make them feel most comfortable during a bath. Instead of a full bath, perhaps a patient would prefer only a partial bath, with a family member performing the bathing of private body areas. The patient may also defer part of the hygiene care. If, in your judgement, hygiene is critical to prevent developing or worsening problems, such as skin breakdown, you must take the time to understand the patient's concerns and negotiate a mutually satisfactory solution to the problem.

Patients at Risk for Hygiene Problems

Some patients present risks that require more attentive and rigorous hygiene care (Table 37-5). These risks may result from side effects of medications, a lack of knowledge, an inability to perform hygiene, or a physical condition that potentially injures the skin or other structures. An immobilized patient who has a fever, for example, requires more frequent bathing to minimize perspiration on the skin, and more frequent turning and positioning to reduce the risk of skin breakdown.

Anticipate whether a patient is predisposed to such risks and follow through with a complete assessment. For example, if a patient is receiving chemotherapy, the treatment has a risk of destroying the normal flora in the mouth, allowing for the overgrowth of opportunistic bacteria. Therefore, the oral examination should be more thorough and detailed, involving all surfaces of the tongue and mucosa. If a patient is diaphoretic, special attention should be given to body areas such as underneath the breasts and the perineal area, where moisture may collect and irritate skin surfaces. You should anticipate problems created by these risks and provide appropriate preventive care. Your assessment should include a review of the patient's medical and surgical histories, medications, and specific risk factors.

Special Considerations in Hygiene Assessment

Depending on the type of hygiene you are planning to provide, you should conduct certain focused assessments. Before giving foot care, you should assess the type of footwear worn by a patient. Children or young adults who frequently fail to wear socks may have excess perspiration that promotes fungal growth. Tight or poorly fitting shoes, socks, garters, or knee-high nylon stockings may cause skin irritation and interfere with circulation to the feet. You should also assess whether patients wear clean footwear daily because repeated use of soiled footwear can lead to infection. If patients have diabetes mellitus or another peripheral vascular disease, it is extremely important that they wear appropriate footwear. Extra-wide and extra-deep shoes accommodate bunions or hammer toes. Cushioned inner soles help redistribute pressure on the metatarsal head. Patients may need to be referred to a podiatrist and orthotic footwear specialist.

It is also important to assess patients' eating patterns before providing oral care. Ask patients whether problems are noted with chewing, swallowing, or the fit of their dentures, if any. Patients may have changed the type of food in their diet as a result of chewing difficulties. The presence of an ulcer or irritation may impair chewing and cause patients to avoid eating. This is common in older adults with poorly fitting dentures.

Patient Expectations

As is the case in any nursing assessment, it is important to know what patients expect from nursing care. For hygiene care, patients may simply expect to have hygiene preferences and practices applied in the health care setting. You can assess patients' expectations by asking questions such as "To make you most comfortable and feeling at home, how can I best perform your bath and personal care?" or "How can we help you care for your teeth, nails, and hair, now that you are at home?"

Understanding your patients' expectations and applying them in practice is important in establishing a caring relationship. Truly individualizing hygiene care shows respect for

► TABLE 37-5 Health Risks and Implications for Hygiene

Risks	Hygiene Implications
Oral Problems Inability to use upper extremities due to paralysis, weakness, or restriction (e.g., cast or dressing) Dehydration, inability to take fluids or food by mouth Presence of nasogastric or oxygen tubes; mouth breathers Chemotherapeutic drugs Other medications (antihistamines) Over-the-counter lozenges, cough drops, antacids, and chewable vitamins Radiation therapy to head and neck Oral surgery, trauma to mouth, placement of an oral airway Immunosuppression; altered blood clotting Diabetes mellitus	Patient lacks upper extremity strength or dexterity needed to brush teeth (Miller, 2009). Dehydration causes excess drying and fragility of the mucosa, and increases the accumulation of secretions on the tongue and gums. These cause drying of the mucosa. Drugs kill rapidly multiplying cells, including normal cells lining the oral cavity. Ulcers and inflammation can develop. Can cause a decrease in saliva production, which leads to thicker mucus and dryness of the oral mucosa (xerostomia). Medications may contain large amounts of sugar. Repeated use increases sugar or acid content in mouth. Radiation therapy decreases the function of the salivary glands, which can contribute to stomatitis (Cummings-Winfield & Olson, 2010). These cause trauma to the oral cavity with swelling, ulcerations, inflammation, and bleeding. These conditions predispose to inflammation and bleeding gums. Patients with diabetes are prone to dryness of the mouth, gingivitis, periodontal disease, and tooth loss.
Skin Problems Immobilization Reduced sensation due to stroke, spinal cord injury, diabetes, local nerve damage Limited protein or caloric intake and reduced hydration (e.g., caused by fever, burns, gastrointestinal alterations, poorly fitting dentures) Excessive secretions or excretions on the skin from perspiration, urine, watery fecal material, and wound drainage Presence of external devices (e.g., casts, restraint, bandage, dressing) Vascular insufficiency	Dependent body parts are exposed to pressure from underlying surfaces. The inability to turn or change position increases the risk for pressure ulcers. Patient does not receive the normal transmission of nerve impulses when excessive heat or cold, pressure, friction, or chemical irritants are applied to skin. Limited caloric and protein intakes predispose to impaired tissue synthesis. The skin becomes thinner, less elastic, and smoother, with a loss of subcutaneous tissue. Poor wound healing may result. Reduced hydration impairs skin turgor. Moisture is a medium for bacterial growth and can cause local skin irritation, softening of epidermal cells, and skin maceration. A device can exert pressure or friction against the skin's surface. Arterial blood supply to tissues is inadequate, or venous return is impaired, causing decreased circulation to the extremities. Tissue ischemia and breakdown may occur. The risk for infection is high.
Foot Problems Inability to bend over or see clearly	Patient is unable to fully visualize the entire surface of each foot, impairing his or her ability to adequately assess the condition of skin and nails.
Eye Care Problems Reduced dexterity and hand coordination	Physical limitations create an inability to safely insert or remove contact lenses.

your patients' needs. As you learn what each patient expects, this information can be incorporated into the individual's plan of care (see the Planning section later).

❖ Nursing Diagnosis

Your assessment reveals the condition of the skin, oral cavity, and other tissues, as well as a patient's need for and ability to meet personal hygiene needs. As you review all data gathered, think about your knowledge pertaining to pre-existing conditions, and then look for clusters of data suggesting a problem trend. For example, an older adult with degenerative arthritis can present with pain in the joints, weakness, mobility limitations in the dominant hand, and a generally unkempt

appearance. A closer review of assessment data reveals defining characteristics of an inability to wash body parts and difficulty turning and regulating a water faucet. The nursing diagnosis of *bathing/hygiene self-care deficit* is supported and becomes part of the plan of care. The accurate selection of nursing diagnoses requires critical thinking to identify actual or potential health problems. Assessment activities must be thorough in identifying all appropriate defining characteristics so that an accurate diagnosis can be made (Box 37-5).

The focus of nursing interventions depends on whether a patient has an actual alteration (e.g., impaired tissue integrity) or is at risk for a problem (e.g., risk for impaired oral mucous membrane). The patient with an actual alteration requires extensive hygiene care, which is often more thorough than

BOX 37-5 NURSING DIAGNOSTIC PROCESS

Assessment Activities	Defining Characteristics	Nursing Diagnosis
Observe patient's attempt to bathe self either in bed or at bathroom sink. (Note: Be sure positioning does not restrict potential movement.)	Unable to wash body or body parts	Self-care deficit in bathing or hygiene related to upper extremity weakness and generalized fatigue
Assess patient's upper extremity strength, range of motion, and coordination.	Restricted upper extremity range of motion and strength Coordination adequate	
Ask patient about level of fatigue after bathing.	Complains of fatigue and needs to rest after bathing	
Obtain vital signs before and after bathing.	Pulse elevated from 90–110 beats per minute, blood pressure stable, respirations elevated from 16–22 breaths per minute	

routine care. For example, if the patient has skin breakdown, you must initiate care more frequently to keep intact skin surfaces clean and dry and to eliminate factors such as moisture or drainage that can worsen the condition of the skin. You also provide care to promote healing of injured skin surfaces (see Chapter 46). If the patient is at risk for a problem, you institute preventive measures. In the case of risk for impaired oral mucous membranes, you keep the mucosa well hydrated, minimize foods irritating to tissues, and provide cleansing that soothes and reduces tissue inflammation.

The identification of related factors guides in the selection of nursing interventions. Diagnoses of *impaired oral mucous membrane related to malnutrition* and *impaired oral mucous membrane related to chemical trauma* require very different interventions. When malnutrition is a causal factor, you confer with a dietitian for appropriate dietary supplements and incorporate patient education into the plan. When mucosa are injured as a result of chemical trauma from chemotherapy, techniques for cleansing and hydrating inflamed tissues and eliminating sources of irritation are the focus of nursing care. Although many nursing diagnoses associated with hygiene problems are possible, the following are a few of the more common diagnoses:

- *Impaired dentition*
- *Fatigue*
- *Ineffective health maintenance*

Figure 37-6 Critical thinking model for hygiene planning.

- *Risk for infection*
- *Deficient knowledge about hygiene practices*
- *Impaired physical mobility*
- *Impaired oral mucous membrane*
- *Self-care deficit, bathing/hygiene, dressing/grooming, toileting*
- *Chronic low self-esteem*
- *Risk for impaired skin integrity*
- *Ineffective tissue perfusion*

❖ Planning

During planning, you synthesize information from multiple resources (Figure 37-6). Professional nursing standards and evidence-informed clinical guidelines are especially important to consider when developing a care plan for the patient. For example, the clinical practice guidelines of the Canadian Diabetes Association (2008) offer valuable foot care guidelines for diabetic patients. Critical thinking ensures that the patient's plan of care integrates knowledge about the individual patient, including preferences, health status, equipment needed, assistance available, and previous experience in providing hygiene care. Certain patients have multiple nursing diagnoses. The concept map (Figure 37-7) shows graphically how numerous nursing diagnoses can be interrelated.

Goals and Outcomes

You and the patient work together to identify goals and expected outcomes and to develop an individualized care plan based on the patient's nursing diagnoses (Box 37-6). Goals are established with the patient's self-care abilities and resources in mind and focus on maintaining or improving the condition of the skin and mucosa, oral mucosa, or dental hygiene, for

Figure 37-7 Concept map for a patient with Alzheimer's disease and hygiene needs. *ADLs*, Activities of daily living; *IADLs*, instrumental activities of daily living.

> BOX 37-6 NURSING CARE PLAN

Self-Care Deficit: Hygiene (Foot Care) Related to Visual Impairment and Knowledge Deficit

Assessment

Mr. James is a 77-year-old who has had type 1 diabetes mellitus for 30+ years. He was recently admitted to hospital for uncontrolled blood glucose levels. Examination of his feet reveals reddened areas over the bony prominences of the toes and calluses to the soles of the feet and to both heels. Mr. James's toenails are unkempt, yellow, and thickened. He states that he is unable to see well enough to trim his toenails because he has cataracts.

Assessment Activities

Inspection

Inspect the feet for dry, rough skin, fissures, calluses, lesions, blisters, inflammation, edema.

Rationale: Daily inspection is especially important for those patients at an increased risk for developing pressure ulcers. Prevention: Early recognition of risk factors associated with diabetic foot issues.

Inspect the toenails for discoloration, thickness, and any abnormal findings (e.g., ingrown toenails).

Rationale: Monitor for signs of infections, redness, erythema for prevention and early recognition.

Palpation

Palpate the dorsalis pedis and posterior tibial pulses.

Rationale: Decreased circulation due to neuropathy and vascular insufficiency can lead to the development of foot ulcers.

Assess skin temperature and compare bilaterally.

Rationale: Decreased circulation increases patient's risk for development of diabetic foot ulcers.

Findings and Defining Characteristics

Redness over bony prominences of toes
Calluses on soles of feet and heels

Unkempt, yellow, thickened toenails

Pedal pulses weak bilaterally

Feet are cool to touch bilaterally

Continued

► BOX 37-6 NURSING CARE PLAN—cont'd

Assessment Activities

Palpate for edema, tenderness.

Rationale: Bilateral dependent edema occurs with diabetic neuropathy.

Assess sensation.

Rationale: Neuropathy is a major risk factor for the development of foot ulcers.

Assess range of motion.

Protection

Assess type and condition of footwear.

Hygiene

Inquire about present foot care practices.

Inspect feet for odour, cleanliness, excessive dryness or moisture, and the condition of the nails.

Findings and Defining Characteristics

No edema or tenderness

Decreased sensation bilaterally

Range of motion within normal limits

Patient wears ill-fitting shoes that are well worn, have slippery soles, and are approximately 10 years old
Socks are tight fitting around the ankles and have holes on the soles

Mr. James does not have any specific foot care practices, does not use moisturizing lotion, and has never visited a foot care specialist

Excessive dryness
No odour is present
Nails are unkempt, long, thickened, and discoloured

Nursing Diagnosis: Self-care deficit: Hygiene (foot care) related to visual impairment and knowledge deficit.

Planning

Goals (Nursing Outcomes Classification)*

Attain baseline of patient's current knowledge and practices regarding foot hygiene and access to resources.

Increase patient's knowledge on the importance of foot hygiene.

Eliminate underlying cause of redness over bony prominences and calluses.

Patient is able to describe and demonstrate proper technique for foot hygiene.

Nails are clean and well-trimmed.

Intervention (Nursing Interventions Classification)[†]

Assess patient's knowledge and current foot care practices.
Assess patient's ability to perform ADLs and IADLs.

Provide instruction on the need for and the importance of daily inspection of the feet for signs of skin breakdown (e.g., redness, blisters, abrasions, ulcers); friction and calluses from ill-fitting footwear; and daily hygiene.

Encourage patient to wear appropriate, well-fitting shoes and socks that are free from damage and not constricting.

Demonstrate appropriate technique for foot inspection, hygiene, and application of moisturizing lotion.

Toenails should be cut straight across to prevent ingrown toenails. Refer patient to foot specialist for nail care if necessary.

*Outcome classification labels from Moorhead, S., Johnson, M., Maas, M. L., & Swanson, E. (Eds.). (2008). *Nursing outcomes classification (NOC)* (4th ed.). St Louis, MO: Mosby.

[†]Intervention classification labels from Bulechek, G. M., Butcher, H. K., & McCloskey Dochterman, J. (Eds.). (2008). *Nursing interventions classification (NIC)* (5th ed.). St Louis, MO: Mosby Elsevier.

Evaluation

Patient's foot hygiene practices have improved. Feet are clean, skin integrity is maintained, feet are free from injury, and there is a decrease in dryness. Patient is seeing a foot care specialist every 3 to 4 weeks for nail care, callus removal, and foot assessment. Appropriate, well-fitting footwear is worn.

example. Outcomes should be appropriate, realistic, measurable, and achievable within patient limitations.

When providing for patient hygiene, you care for a variety of patients with different self-care abilities and needs. For example, for a patient who has hemiparesis after a cerebral vascular accident, you and the patient might develop the following goal: "Patient's musculoskeletal system remains free of breakdown or contractures." A series of realistic individualized

expected outcomes would then be established to assist the patient in meeting this goal. These outcomes may include the following:

- Patient's skin is clean, dry, and intact without signs of inflammation.
- Patient's skin remains elastic and well hydrated.
- Patient's range of joint motion remains within normal limits on both affected and unaffected sides.

Setting Priorities

The patient's condition influences the plan for delivering hygiene. A seriously ill patient usually needs a daily bath because body secretions accumulate and can lead to skin breakdown. An older patient at home may require a visit from a home care aide to assist with a tub bath. Patients who are normally inactive during the day and have skin that tends to be dry may need to bathe only twice a week. You must plan for necessary assistance for patients who are weakened or possess poor coordination. For example, a patient who has hemiparesis and has difficulty getting out of the tub should have a tub chair, handrails, or extra personnel available for help.

Timing is also important in planning hygiene. Being interrupted in the middle of a bath to undergo a diagnostic procedure can frustrate and embarrass a patient. After extensive diagnostic tests (e.g., a stress test), it may be best to delay hygiene and allow a patient to rest.

Continuity of Care

It is important to plan for care throughout the hospital stay, from admission to discharge, whether to a rehabilitation facility or back home. When a patient needs assistance as a result of a self-care limitation, the family becomes a valuable resource. Family members can usually assist with hygiene measures but may need support and guidance in adapting techniques to fit patient limitations. You must be aware of equipment and procedures that were used while the patient was in the hospital or facility so that the patient and family are knowledgeable about the care, have the skill needed to provide the care, and have access to necessary equipment. In addition, various community resources may be needed. For example, if you are involved in the care of a homeless patient, you may need to be aware of the location of clothing distribution centres for basic hygiene supplies or a shelter where bathing facilities are available. Forming partnerships with social workers or staff in local area churches and schools can assist in ensuring that patients have the resources they need to maintain hygiene.

❖ Implementation

Providing hygiene is a very basic part of a patient's care. The use of caring practices helps to alleviate the patient's anxiety and promote comfort and relaxation while you perform each hygiene measure. For example, while giving a patient a bath and changing a gown, use a gentle approach in turning and repositioning the patient and use a soft, gentle voice while conversing with the patient to help relieve any fears or concerns. For patients with symptoms such as pain or nausea, administering symptom relief therapies before starting hygiene care helps to prepare the patient for the procedure.

Another important part of implementation is assisting patients to administer their own hygiene. This includes educating patients on proper hygiene techniques and connecting patients with the community resources necessary to enable them to perform hygiene care. The same patients at risk for hygiene problems are those in greatest need of understanding their risks, knowing the implications, and having the information they need to make choices about when and how hygiene is performed.

Health Promotion

In primary health care settings, educate and counsel patients and families on appropriate hygiene techniques. A new mother

► BOX 37-7

Educating Patients About Hygiene Care

- Make instructions relevant. After assessing a patient's knowledge, motivation, and health beliefs, provide information that relates to the patient's situation and will be most useful in resolving the patient's problem. For example, when offering foot care instruction to a patient with diabetes mellitus, explain how the circulation to the feet can be impaired and how that poses a risk for poor healing and infection should the skin become cut or broken.
- Adapt teaching of techniques to the patient's personal bathing facilities. Not all patients will have the ideal situation that exists in a health care setting (e.g., easily accessible shower or a bedside table to place over a bed). Use the facilities or equipment that the patient has so that personal care items are easy to reach, the patient's safety is ensured, and the patient feels comfortable when performing hygiene. For example, a young mother may feel more comfortable bathing an infant in a baby bath chair.
- Teach the patient steps to take to avoid injury. Almost any hygiene procedure can pose risks (e.g., cutting a nail too close to the skin, failing to adjust the water temperature of a bath, or using tap water for contact lens care). Any instruction you provide must clearly outline safety risks.
- Reinforce infection control practices. Damage to the skin, mucosa, eyes, or other tissues creates an immediate risk for infection. Be sure the patient understands the relationship between healthy and intact skin and tissues, hand hygiene practices, and the prevention of infection.

needs assistance in learning how to bathe her newborn infant. An older adult needs to become informed about the importance of regular ear care to avoid hearing deficits resulting from accumulated cerumen. When assisting patients, maintain the standards for hygiene illustrated in this chapter and incorporate adaptations as needed to their lifestyle, living arrangements, abilities, and preferences. Guidelines to assist you in providing education to patients about hygiene are presented in Box 37-7.

Acute and Restorative Care

Nursing knowledge and skills needed for performing hygiene care are consistent across all health care settings where acute and restorative care are provided. In addition, some of the skills in this section are applicable in areas of health promotion.

In health care settings where patients receive direct nursing care, a variety of scheduled hygiene measures are provided (Box 37-8). Times may change because of factors affecting your organization or scheduling of care such as planned diagnostic and treatment procedures, the patient's need for more hygiene, or your work assignment. In long-term care facilities, the schedule for hygiene may be less frequent.

Bathing and Skin Care

Bathing and skin care are a part of total hygiene. The extent of patients' bath and the methods used for bathing depend on their physical abilities, health problems, and the degree of hygiene required. If patients are physically dependent or cognitively impaired, increase skin assessment and provide skin care directed toward reducing the risk for skin breakdown. When bathing cognitively impaired patients, consider their

► BOX 37-8

Hygiene Care Schedule in Acute and Long-Term Care Settings**Early Morning Care**

If you work the night shift, you may be required to provide basic hygiene to patients getting ready for breakfast, scheduled tests, or early morning surgery. Early morning care (often referred to as "A.M. care") includes offering a bedpan or urinal if the patient is not ambulatory, washing the patient's hands and face, and assisting with oral care.

Routine Morning Care

Before or after breakfast, assist by offering a bedpan or urinal to patients confined to bed; providing a bath or shower; giving perineal care; giving oral hygiene and foot, nail, and hair care; giving a back rub; changing the patient's gown or pyjamas; changing the bed linens; and straightening the patient's bedside unit and room. This is often referred to as "complete A.M. care."

Afternoon Care

Hospitalized patients often undergo many exhausting diagnostic tests or procedures in the morning. In rehabilitation centres, patients may participate in physiotherapy during the morning. Afternoon hygiene care includes washing the hands and face, assisting with oral care, offering a bedpan or urinal to those patients who are not ambulatory, and straightening bed linen.

Evening, or Hour-Before-Sleep, Care

Before bedtime, offer personal hygiene care that helps a patient relax to promote sleep. Evening care, or P.M. care, may include changing soiled bed linens, gowns, or pyjamas; assisting the patient in washing the face and hands; providing or assisting with oral hygiene; giving a back massage; and offering a bedpan or urinal to nonambulatory patients. Ask patients if they would like a beverage, such as juice, if permitted.

special needs and challenges (Box 37-9). These patients can easily become afraid, may use physical and verbal aggressive behaviours to avoid bathing, and may also display self-injurious behaviours (Miller, 2009).

A **complete bed bath** is used with patients who are totally dependent and require total hygiene care. It is an activity that can be exhausting for patients, even if you provide all the care. You must anticipate and assess whether patients are physically able to tolerate a complete bath. Measuring patients' vital signs before, during, and after the bath provides a measure of their physical tolerance. A **partial bed bath** involves bathing only those body parts that would cause discomfort or odour if not cleansed, and those areas not easily reached by the patient. This includes perineal care. Aging or dependent patients in need of only partial hygiene and self-sufficient bedridden patients unable to reach all body parts receive partial bed baths. Carefully assess patients to determine the amount of assistance required during hygiene care. Skill 37-1 outlines the procedures for bathing a bedridden client.

When administering a complete or partial bath, it is important to assess the condition of the skin to determine which type of cleansing product is necessary or whether the patient requires daily bathing. Patients with excessively dry skin are predisposed to skin impairment. You may decide to skip a bath for a day or bathe only badly soiled areas. The use of a soap that contains emollients is another option. Lubricating the skin with lotion can also help reduce dryness.

* BOX 37-9

EVIDENCE-INFORMED PRACTICE GUIDELINE**Bathing Patients Who Have Dementia or Alzheimer's Disease**

Provide individualized and flexible patient-centred care:

- Obtain bathing history—what works, what doesn't work.
- Identify bathing preferences from the patient, other caregivers, or family.
- Determine the method that is least distressing to the patient (e.g., soaking feet in the bathtub; use of prepackaged commercial bath cleansing products [see Figure 37-8]; no-rinse shampoo cap—if hair washing causes the patient distress).
- If patient fears water, try using coloured water or drawing a bubble bath.
- Prepare the bath environment in advance, adequate lighting, necessary supplies (soap, shampoo, towels, etc).
- Minimize the time the patient is unclothed, and ensure the bathing environment is warm.
- Use distraction and negotiation instead of demands (e.g., give the patient a washcloth to keep hands occupied).
- Minimize noise in the bathing area or play their favorite music softly in the background.
- Set priorities regarding which body parts need bathing and which parts can be "skipped" (e.g., separate hair washing from bathing).
- Assess whether the patient requires glasses or a hearing aid, which can assist with communication (remove aids as required during bathing after communicating your intent to the patient).
- Praise the patient's accomplishments.

Retrieved from www.alzheimer.ca/en/Living-with-dementia/Day-day-living/Personalcare/Bathing; and Rader, J., Barrick, A. L., Hoeffer, B., Sloane, P. D., McKenzie, D., Talerico, K., & Glover, J. (2006). The bathing of older adults with dementia: Easing the unnecessarily unpleasant aspects of assisted bathing. *AJN*, 106(4), 40–48.

The tub bath or shower can be used to give a more thorough bath than a bed bath. Safety is of primary concern because the surface of a tub or shower stall is slippery. In some settings, it is necessary to obtain a physician's or nurse practitioner's order for a shower or tub bath. In some agencies, showers are equipped with a chair for patients with weakness or poor balance. Both tubs and showers should be equipped with grab bars for patients to hold on to during their entry and exit and when manoeuvring. Patients vary in how much assistance they need. Regardless of the type of bath the patient receives, the following guidelines should be used:

- **Provide privacy.** Close the door or pull the room curtains around the bathing area. While bathing the patient, expose only the areas being bathed.
- **Maintain safety.** Keep the side rails up while away from the patient's bedside. This is critical for dependent, debilitated, and unconscious patients. (Note: When side rails are used as a restraint, a physician's order may be needed. Check your agency's policy.) Place the call light within the patient's reach if you are leaving the room temporarily.

► SKILL 37-1 Bathing a Patient

Delegation Considerations

Skills of bathing may be delegated to an unregulated care provider. Instructions about the following should be provided:

- The importance of not massaging reddened skin areas
- The clarification of early signs of impaired skin integrity
- The importance of reporting changes in the patient's skin
- Proper positioning of an in-dwelling catheter during perineal care
- The importance of reporting any perineal drainage, excoriation, or rash observed

Equipment

- Washcloths and bath towels
- Wash basin
- Bath blanket (warm, if possible)
- Cleansing solution (agency or patient specific)
- Personal hygiene items (unscented deodorant, powder, lotion,)
- Clean hospital gown or patient's own pyjamas or gown
- Bed linen
- Linen bag
- Disposable gloves
- Disposable wipes
- Bedpan or urinal

Procedure

STEPS

General Instructions

1. Review orders for specific safety measures concerning the patient's movement, positioning, or isolation precautions.
2. Explain procedure, and ask patient for suggestions on how to prepare supplies. Encourage and promote independence by asking the patient how much of the bath he or she wishes to complete.
3. Assess patient's ability to perform self-care and allow patient to perform as much of the bath as possible.
4. Assess patient's tolerance for activity, comfort level, cognitive ability, and musculoskeletal function.

RATIONALE

- Prevents accidental injury to the patient during bathing activities.
- Determines level of assistance required by the patient.
- Promotes patient's cooperation and participation.
- Promotes patient's comfort and provides an opportunity to include cultural or personal hygiene preferences in hygiene care.
- Patient participates in plan of care.
- Determines the amount of assistance required, the need for specialized equipment or additional personnel.
- Encourages and promotes independence.
- Determines patient's ability to perform self-care and level of assistance required. Also determines type of bath to administer (e.g., tub bath or partial bed bath).

Critical Decision Point: Patients whose level of independence and mobility change frequently may require more or less assistance during bathing.

5. Assess patient's bathing preferences: frequency, type of hygiene products, and other factors related to patient preferences.
6. Ask whether patient has noticed any problems or unusual marks on skin. Observe the skin throughout the procedure, paying particular attention to areas that were previously soiled or reddened or showed early signs of breakdown.
7. Begin complete or partial bed bath, or tub/whirlpool bath or shower.
 - A. Complete or partial bed bath
 - (1) Close room doors and draw the room divider curtain.
 - (2) Prepare equipment and supplies.
 - (3) For nonambulatory patients, offer a bedpan or urinal. Provide a towel and washcloth for perineal care afterward.
 - (4) Perform hand hygiene. If patient's skin is soiled with drainage or body secretions, put on disposable gloves. Ensure the patient is not allergic to latex.
 - (5) Place hospital bed at appropriate level, lower side rail closest to you. Assist patient in assuming a comfortable position, preferably supine. Bring or have the patient move toward side closest to you.
 - (6) Loosen the top covers. Place bath blanket over the top sheet. Remove top sheet from under the blanket. If possible, have patient hold bath blanket while you withdraw sheet. Optional: Use the top sheet when a bath blanket is not available.

- Encourages and promotes patient participation.
- Provides information to direct physical assessment of skin during bathing.
- Privacy ensures patient's mental and physical comfort.
- Reduces transmission of microorganisms and avoids interrupting the procedure or leaving the patient unattended to retrieve missing equipment.
- Patient will feel more comfortable after voiding. Prevents the interruption of bath.
- Reduces transmission of microorganisms.
- Raising the height of the bed to the appropriate position facilitates proper body mechanics. Maintains patient's comfort throughout procedure. Minimizes strain on back muscles because you do not have to reach across bed.
- Removal of top linens prevents them from becoming soiled or moist during the bath. Blanket provides warmth and privacy. The patient is not exposed unnecessarily.

Continued

► SKILL 37-1 Bathing a Patient—cont'd

video

- (7) If top sheet is to be reused, fold it for replacement later. If not, dispose in linen bag, taking care not to allow linen to contact uniform.
 - (8) Assist patient with oral hygiene. See Skill 37-3.
 - (9) Remove patient's gown or pyjamas. If the patient has an IV infusing and the gown has snaps, simply unsnap and remove the gown without disconnecting the IV tubing. If the gown does not have snaps, remove gown from the arm without IV first; then lower the IV container or remove from the pump and slide the gown covering the affected arm over the tubing and container. Rehang IV container and check flow rate (see Step 7A(9) illustrations) or reset pump rate. Do not disconnect the tubing. If an extremity is injured or has reduced mobility, begin removal from the unaffected side.
- Proper disposal prevents transmission of microorganisms.
 - Provides full exposure of body parts during bathing. Undressing unaffected side first allows easier manipulation of gown over body part with reduced range of motion (ROM).
 - Manipulation of IV tubing and container will possibly disrupt flow rate.

Step 7A(9) A, Remove patient's gown. B, Remove IV from pole. C, Slide IV tubing through arm of patient's gown. D, Rehang IV bag and check flow rate.

Critical Decision Point: If available, be sure that patients with an IV or upper extremity injury have a gown with snap or tie sleeves; this ensures easy access to the upper extremities during hygiene.

Critical Decision Point: When an IV pump is used, it may be appropriate to manually adjust the IV flow rate to keep-vein-open (KVO) and remove the IV tubing from the pump (check agency policy). Once the gown has been removed, reset the pump to the prescribed IV flow rate (see Chapter 39).

- (10) Raise the side rail. Fill a wash basin two-thirds full with warm water. Have patient place fingers in water to test temperature tolerance. Change the water as necessary throughout the bath.
 - (11) Remove pillow, if allowed, and raise head of the bed 30–45 degrees. Place bath towel under the patient's head. Place a second bath towel over patient's chest.
 - (12) Immerse washcloth in water and wring thoroughly. If desired, fold the washcloth around the fingers of your hand to form a mitt (see Step 7A(12) illustration).
- Raising side rail maintains the patient's safety as you leave the bedside. Warm water promotes comfort, relaxes muscles, and prevents unnecessary chilling. Testing the temperature prevents accidental burns.
 - Removal of the pillow makes it easier to wash the patient's ears and neck. The placement of towels prevents soiling of the bed linen and bath blanket.
 - A mitt retains water and heat better than a loosely held washcloth and prevents splashing and cold edges from brushing against the patient.

► SKILL 37-1 Bathing a Patient—cont'd

video

- (13) Inquire whether the patient is wearing contact lenses. Wash patient's eyes with plain warm water. Use a different section of mitt for each eye. Move mitt from inner to outer canthus (see Step 7A(13) illustration). Soak any crusts on eyelid for 2–3 minutes with damp cloth before attempting removal. Dry eyes thoroughly but gently.

Step 7A(12) Steps for folding washcloth to form a mitt.

- (14) Ask whether patient prefers to use soap on his or her face. Wash, rinse, and thoroughly dry all areas of the face, neck, and ears. (Men may wish to shave at this point or after the bath.)
- (15) Expose patient's arm that is farthest from you and place bath towel lengthwise under the arm.
- (16) Bathe arm using long, firm strokes from distal to proximal areas (fingers to axilla). Raise and support arm as needed while thoroughly washing the axilla (see Step 7A(16) illustration).

Step 7A(16) Washing from fingers to axilla.

- (17) Rinse and dry arm and axilla thoroughly. If patient uses deodorant or talcum powder, apply it.
- (18) Fold bath towel in half and lay it on the bed beside the patient. Place a basin on the towel. Immerse patient's hand in water. Allow hand to soak for 3–5 minutes before washing hand and fingernails (see Skill 37-2). Remove basin and dry hand well.
- (19) Cover the arm with bath blanket or towel. Repeat steps 15–18 for the other arm.

- Soap irritates eyes. The use of separate sections of mitt reduces infection transmission. Bathing the eye from inner to outer canthus prevents secretions from entering nasolacrimal duct. Pressure can cause internal injury.

Step 7A(13) Wash eye from inner to outer canthus.

- Soap tends to dry the face, which is exposed to air more than other body parts.
- Prevents soiling of bed. Washing far side first eliminates contaminating clean areas once they are washed.
- Soap lowers the surface tension of the skin and facilitates the removal of debris and bacteria when friction is applied during washing. Long, firm strokes stimulate circulation. Movement of the arm exposes the axilla and exercises the joint's normal ROM.

- Excess moisture causes skin maceration or softening. Deodorant controls body odour.
 - Soaking softens cuticles and calluses of the hand, loosens debris beneath nails, and enhances the feeling of cleanliness. Thorough drying removes moisture from between fingers.
- Note:* Do not soak if the patient is diabetic or is cognitively impaired and unable to understand the procedure.

Critical Decision Point: If a patient is at risk for falls, be sure the two side rails are up before obtaining fresh water or other supplies. Remember, side rails cannot be used as a restraint unless ordered.

Continued

► SKILL 37-1 Bathing a Patient—cont'd

video

- (20) Cover patient's chest with a bath towel, and fold bath blanket down to the umbilicus. With one hand, lift edge of towel away from patient's chest. With washcloth or mittened hand, bathe chest using long, firm strokes. Take special care to wash skinfolds under the patient's breasts. Keep patient's chest covered between wash and rinse periods. Dry well.
 - (21) Place bath towel lengthwise over patient's chest and abdomen. (Two towels may be needed.) Fold blanket down to just above the pubic region.
 - (22) With one hand, lift the bath towel. With mittened hand, bathe the abdomen, giving special attention to bathing the umbilicus and abdominal folds. Keep the abdomen covered between washing and rinsing. Dry well.
 - (23) Cover patient's chest and abdomen with top of the bath blanket or bath towels. Expose far leg by folding blanket toward midline. Be sure other leg and perineum are covered.
 - (24) Place bath towel lengthwise under the far leg and, using firm strokes (unless contraindicated), wash, rinse, and dry thoroughly. Support the leg with one hand if patient is unable to support it.
- Draping prevents unnecessary exposure of body parts. The towel maintains warmth and privacy. Secretions and dirt collect easily in areas of tight skinfolds. Skinfolds are susceptible to excoriation if not cleaned and dried properly.
 - Prevents chilling and unnecessary exposure of body parts.
 - Moisture and sediment that collect in skinfolds predispose skin to maceration and irritation.
 - Maintains patient's warmth and comfort. Prevents chilling and unnecessary exposure.
 - Promotes venous return.

Critical Decision Point: Patients with a history of deep vein thrombosis (DVT) or hypercoagulation disorders should not have their lower extremities washed with long firm strokes.

- (25) Cleanse the foot, making sure to bathe between toes. Clean and clip nails as per physician or nurse practitioner orders (see Skill 37-2). Dry well. If skin is dry, apply lotion.
- Secretions and moisture can accumulate between the toes. Lotion helps retain moisture and soften the skin.
 - Patient's own nail clippers should be used to avoid the transmission of microorganisms.

Critical Decision Point: Do not massage any reddened area on the patient's skin as it can increase the risk of skin breakdown (Youell & Wright, 2010).

- (26) Repeat Steps 23–25 for the other leg and foot.
 - (27) Assist patient in assuming a prone or side-lying position (as applicable). Place the towel lengthwise along the patient's side. Put on disposable gloves if not done so already.
 - (28) Wash, rinse, and dry patient's back from neck to buttocks using long, firm strokes (see Step 7A(28) illustration). Pay special attention to folds of the buttocks and the anus for redness or skin breakdown. Give a back massage (see Chapter 41). Change bath water if necessary and put on disposable gloves.
- Exposes back and buttocks for bathing. Prevents contact with microorganisms in body secretions.
 - Maintains warmth and prevents unnecessary exposure. Skinfolds near buttocks and anus may contain fecal secretions that harbour microorganisms.
 - Prolonged pressure on the sacral area or other bony prominences may lead to the development of pressure ulcers.
 - Changing the water prevents the transfer of microorganisms from the anal area to genitalia.

Step 7A(28) Washing patient's back.

► SKILL 37-1 Bathing a Patient—cont'd

video

(a) Female perineal care

- (a1) Assist patient in assuming a dorsal recumbent position, if not contraindicated. Cover chest and upper extremities with a towel and lower extremities with a bath blanket. Expose only the genitalia. (If patient can wash, covering entire body with a bath blanket may be preferable.) Clean the perineal area. Pay special attention to skinfolds. Patients at risk for infection of the genitalia, urinary tract, or reproductive tract include those with in-dwelling catheters or fecal or urinary incontinence. If fecal material is present, enclose in a fold of underpad and remove with disposable wipes.
- (a2) Wash labia majora. Wipe from the perineum to the rectum. Repeat on the opposite side using a different section of the washcloth.
- (a3) Separate the labia with your nondominant hand, exposing the urethral meatus and vaginal orifice. Wash downward from the pubic area toward the rectum in one smooth stroke (see Step 7A(28)(a3) illustration). Use a separate section of cloth for each stroke. Cleanse thoroughly around the labia minora, clitoris, and vaginal orifice.
- (a4) Assist patient to a comfortable position.
- (a5) Remove disposable gloves and perform hand hygiene.

(b) Male perineal care

- (b1) Lower the side rails, and assist patient to a supine position. Note restriction in mobility. Patients at risk for infection of the genitalia, urinary tract, or reproductive tract include uncircumcised males and patients with in-dwelling catheters or fecal or urinary incontinence.
- (b2) Gently raise the penis, and place a bath towel underneath. Gently grasp the shaft of penis. If the patient is uncircumcised, retract the foreskin (see Step 7A(28)(b2) illustration). If the patient has an erection, perineal care can be deferred until later.

- Provides easy access to genitalia.
- Patients capable of performing partial bath usually prefer to wash their own genitalia.
- Secretions that accumulate on surface of skin surrounding genitalia act as reservoir for infection.
- Cleansing reduces transmission of microorganisms from the anus to the urethra or genitalia.
- Wiping from the perineum to the rectum reduces the chance of transmitting fecal organisms to the urinary meatus.
- Cleansing method reduces the risk of transferring of microorganisms to the urinary meatus (cleansing from area of least contamination to most contamination as secretions that collect around the labia minora facilitate bacterial growth). (For menstruating women or patients with in-dwelling urinary catheters, cleanse with disposable wipes.)
- Prevents the transmission of infection.

- Provides full exposure of male genitalia.
- Patients capable of performing partial bath usually prefer to wash their own genitalia.
- Gentle but firm handling reduces the chance of the patient having erection. Secretions capable of harbouring microorganisms collect underneath foreskin. Cleansing the penis can lead to an erection, which can embarrass both the patient and you.

Step 7A(28)(a3) Cleanse from perineum to rectum (front to back).

- (b3) Wash tip of the penis at the urethral meatus first using a circular motion. Cleanse from the meatus outward. Rinse and dry gently.
- (b4) Return foreskin to its natural position.

Step 7A(28)(b2) Retract foreskin.

- The direction of the cleansing moves from areas of least contamination to most contamination, preventing microorganisms from entering urethra.
- Tightening of the foreskin around the shaft of the penis can cause local edema and discomfort.

Continued

SKILL 37-1 Bathing a Patient—cont'd

- (b5) Wash the shaft of the penis with gentle but firm downward strokes. Pay special attention to the underlying surface of the penis. Rinse and dry thoroughly.
- (b6) Gently cleanse scrotum, making sure to wash underlying skinfolds. Rinse and dry thoroughly.
- (b7) Inspect the surface of external genitalia after cleansing.
- (b8) If the patient has bowel or urinary incontinence, apply a thin layer of skin barrier cream to the buttock, anus, and perineal area.
- (b9) Assist patient to a comfortable position and cover with bath blanket.
- (29) Assist patient in dressing. Comb patient's hair. Women may want to apply makeup, and men may wish to shave at this point. Assist patient to a chair or wheelchair.
- (30) Make the patient's bed (see Skill 37-5).
- (31) Remove soiled linen and place it in linen bag. Clean and replace the bathing equipment. Replace the call light and personal possessions. Leave the room as clean and comfortable as possible.
- (32) Remove disposable gloves (if applied) and perform hand hygiene.

B. Tub or whirlpool bath or shower (verify with agency policy whether a physician's or nurse practitioner's order is needed and whether you need to remain in the room during the patient's bath)

- (1) Check tub or shower for cleanliness. Use cleaning techniques outlined in agency policy. Place rubber mat on tub or shower bottom. Place disposable bath mat or towel on the floor in front of the tub or shower.
- (2) Collect all hygienic aids, toiletry items, and linens requested by the patient. Place within easy reach of the tub or shower.
- (3) Assist patient to the bathroom if necessary. Have patient wear a robe and slippers to bathroom.
- (4) Demonstrate how to use the call signal for assistance.
- (5) Place an "occupied" sign on bathroom door.
- (6) Provide a shower seat or tub chair if needed (see Step 7B(6) illustration). Fill the bathtub halfway with warm water. If patient's sensation is normal, ask patient to test the water, and adjust the temperature if the water is too warm. Explain which faucet controls hot water. If patient is taking shower, turn it on and adjust the water temperature before patient enters the shower stall.

- The underlying surface of penis may have a greater accumulation of secretions.
- Pressure on scrotal tissue can be painful to the patient. Secretions collect between skinfolds.
- Thick secretions may cover underlying skin lesions or areas of breakdown. Evaluation determines the need for additional hygiene.
- Protects skin from excess moisture and toxins from urine and stool.
- Promotes patient's body image.
- Provides a clean environment.
- Prevents the transmission of microorganisms. A clean environment promotes the patient's comfort. Keeping the call light and articles of care within reach promotes the patient's safety.
- Reduces the transmission of microorganisms.
- Cleaning prevents the transmission of microorganisms. Mats prevent slipping and falling.
- Placing items close at hand prevents possible falls when patient reaches for equipment.
- Assistance prevents accidental falls. Wearing a robe and slippers prevents chilling and provides for privacy and comfort.
- Bathrooms are equipped with signalling devices in case a patient feels faint or weak or needs immediate assistance. Patients prefer privacy during bathing if safety is not jeopardized.
- Maintains the patient's privacy.
- The use of assistive devices facilitates bathing and minimizes physical exertion. Adjusting water temperature prevents accidental burns. Older adults and patients with neurological alterations (e.g., spinal cord injury) are at high risk for burns as a result of reduced sensation.

Step 7B(6) Shower seat for patient safety.

► SKILL 37-1 Bathing a Patient—cont'd

- (7) Instruct the patient to use safety bars when getting in and out of the tub or shower. Caution the patient against use of bath oil in tub water.
- (8) Instruct the patient not to remain in tub >20 minutes. Debilitated patients should not be left alone while in the tub. Observe ROM during bath.
- (9) Return to the bathroom when the patient signals, and knock before entering.
- (10) For the patient who is unsteady, drain the tub of water before patient attempts to get out of it. Place a bath towel over patient's shoulders. Assist patient in getting out of tub as needed, and assist with drying. If the patient is weak or unstable, have another person assist.
- Prevents slipping and falling. Oil causes tub surfaces to become slippery.
- Prolonged exposure to warm water may cause vasodilation and pooling of blood, leading to lightheadedness or dizziness. Measures joint mobility.
- Provides privacy.
- Prevents accidental falls. Patient may become chilled as water drains.

Critical Decision Point: Weak or unstable patients need extra assistance in getting out of a tub. Planning for additional personnel is essential before attempting to assist a patient from tub.

- (11) Observe patient's skin, paying particular attention to areas that were previously soiled, reddened, or showed early signs of breakdown.
- (12) Assist patient as needed in donning a clean gown or pyjamas, slippers, and robe. (In a home setting, the patient may don regular clothing.)
- (13) Assist patient to his or her room and a comfortable position in a bed or chair.
- (14) Clean the tub or shower according to agency policy. Whirlpool baths may require special cleaning. Remove soiled linen and place it in a linen bag. Discard disposable equipment in the proper receptacle. Place an "unoccupied" sign on the bathroom door. Return supplies to the storage area.
- (15) Perform hand hygiene.
- Techniques used during bathing should leave skin clean and clear.
- Maintains warmth to prevent chilling.
- Maintains relaxation gained from bathing.
- Prevents the transmission of infection through soiled linen and moisture.
- Reduces the transfer of microorganisms.

Unexpected Outcomes

Areas of excessive dryness, rashes, or irritation, or signs of pressure ulcer on patient's skin

Inflammation of skin and genitalia, with localized tenderness, swelling, and presence of foul-smelling discharge

Patient expresses perineal discomfort

Patient unable to perform perineal care correctly

Patient becomes excessively fatigued and unable to cooperate or participate in bathing

Patient seems unusually restless or complains of discomfort

Related Interventions

- Review your agency's skin care policy regarding special cleansing and moisturizing products.
- Limit the frequency of complete baths.
- Complete a pressure ulcer assessment (see Chapter 46).
- Obtain a special bed surface if patient is at risk for or has skin breakdown.
- Bathe the area frequently to keep it clean and dry.
- Obtain an order for a sitz bath.
- Apply a protective barrier.
- Notify the physician or nurse practitioner and apply prescribed antibacterial or antifungal ointment or cream.
- Increase the frequency of perineal care.
- Assess the perineum for signs of excoriation, swelling, irritation or discharge.
- Review perineal care with the patient.
- Position the patient and have patient observe the cleansing procedure.
- Reschedule bathing to a time when the patient is more rested.
- Patients with cardiopulmonary conditions and breathing difficulties may require a pillow or elevated head of the bed during bathing.
- Notify the physician about changes in the patient's fatigue level.
- Schedule rest periods.
- Consider analgesia before bathing.
- Schedule rest periods before bathing.

Continued

► SKILL 37-1 Bathing a Patient—cont'd

video

Recording and Reporting

- Record the condition of skin and any significant findings (e.g., reddened areas, bruises, nevi, or joint or muscle pain).
- Report any evidence of alterations in skin integrity or increased wound secretions to the person in charge or the physician.
- Record the presence of any abnormal findings (e.g., the character and amount of discharge or condition of the genitalia), and record any related procedure you perform.
- Record the appearance of a suture line, if present.
- Report any break in a suture line or the presence of abnormalities to the person in charge or the physician.
- Record all procedures performed, the amount of assistance provided, and the extent of the patient's participation.

Home Care Considerations

- Assess the patient's tub and shower area for the need for safety devices (e.g., grab bars, bath mats).
- Assess the patient for the need for assistive bathing devices (e.g., shower chair, hand-held shower).
- Instruct caregivers to assess the patient's perineal area daily for signs of infection and skin breakdown.

Older Adult Considerations

- Check the temperature of water carefully as the patient's sensitivity to temperature may be impaired.
- Continent patients may not require bathing every day, especially if dry skin is a problem.

- *Maintain warmth.* The room should be kept warm because the patient is partially uncovered and may easily be chilled. Wet skin causes an excess loss of heat through convection. Control drafts. Keep the patient covered, exposing only the body part being washed during the bath.
- *Promote independence.* Encourage the patient to participate in as much of the bathing activities as possible. Offer assistance when needed.
- *Anticipate needs.* Bring a new set of clothing and hygiene products to the bedside or bathroom.

Bag Baths. An innovative approach to the traditional bed bath was developed because of concern for patients who are predisposed to dry skin and the risk for infection. When wash basins are not cleaned and dried completely after use, contamination with Gram-negative organisms may occur. Successive uses of the basin may cause a patient's skin to harbour more Gram-negative organisms. The "bag bath" (Figure 37-8) is a specially prepared package containing 10 washcloths that are premoistened with a mixture of water and a nonrinsable cleanser. The bag bath package is warmed in a microwave before use, and a different cloth is used for each part of the patient's body. With this technique, the skin air-dries because towel drying removes the emollient that is left behind after the water-cleanser solution evaporates. Health care personnel who have used the bag bath products report shorter bathing times and increased patient satisfaction and staff productivity (Howe, 2008).

Perineal Care. Perineal care is usually part of a complete bed bath (see Skill 37-1). Patients most in need of perineal care are those at greatest risk for acquiring an infection (e.g., patients who have in-dwelling urinary catheters, patients who are recovering from rectal or genital surgery or childbirth, uncircumcised males, patients who are incontinent, or patients who are morbidly obese). In addition, women who are having a menstrual period require good perineal care. Patients who are able to perform self-care should be encouraged to do so. Sometimes you can feel embarrassed when providing perineal care, particularly for patients of the opposite sex. Similarly, patients may feel embarrassed, but this should not cause you to overlook patients' hygiene needs. A professional, dignified, and sensitive approach can reduce embarrassment and put the patients at ease.

Figure 37-8 Commercial bath cleansing pack. **Source:** From Sage Products, Cary, IL. (2009). Retrieved from <http://www.comfortbath.com>.

If patients perform self-care, various problems such as vaginal and urethral discharge, skin irritation, and unpleasant odours may go unnoticed. You must be alert for complaints of burning during urination or localized tenderness, excoriation, or pain in the perineum. You should also inspect your patients' bed linen for signs of discharge.

Back Rub. A back rub or massage is usually performed after a patient's bath. It promotes relaxation, relieves muscular tension, stimulates circulation, and improves sleep (Ebersole et al., 2008). Zullino et al. (2005) posit that massage is associated with a reduction in blood pressure, a reduction in pain, and decreases anxiety and depression. Patients generally report that they are more comfortable after a back rub or massage and find the experience pleasant, regardless of the length of the massage.

When providing a back rub, relaxation can be enhanced by reducing any noise and ensuring that the patient is comfortable. Because some individuals may dislike physical contact, it is important to ask the patient whether he or she would like

* BOX 37-10

EVIDENCE-INFORMED
PRACTICE GUIDELINE**Reducing the Incidence and Prevalence of Pressure Ulcers**

According to a study funded by the Canadian Association of Wound Care (CAWC) in 2003, the mean prevalence rate of pressure ulcers in Canadian health care settings is 26%. Pressure ulcers cause patients stress, pain and suffering, increased length of hospital stay, and increased workload for health care staff. The CAWC estimates that the cost of treating a patient with an uncomplicated pressure ulcer to be \$2400 to \$3200 per month and treatment for a complicated ulcer is estimated to be \$12,000, which includes supplies and nursing care (Orsted et al., 2009). The goal of the Pressure Ulcer Awareness and Prevention (PUAP) program created by the CAWC is to increase awareness of the high cost of pressure ulcers, through education and support, to improve clinical practice, and to create and improve current policies in health care facilities to shift from treatment to prevention of pressure ulcers.

**Nursing Implications**

One of the key components of the nursing history and physical examination is the assessment of the integument for pre-existing conditions or risk assessment for potential breakdown in skin integrity. Risk assessment can be accomplished utilizing the Braden Scale for Assessment of Pressure Ulcer Risk (see Table 46-2, p. 1260) to identify those patients at risk so that strategies can be implemented to reduce the risk. Nurses are in position to have an impact on the financial costs of pressure ulcers to both the health care system and the patients by completing thorough, daily skin assessment during hygiene care or independently for early recognition and early intervention.

References: Orsted, H. L., Rosenthal, S., & Woodbury, M. G. (2009). Pressure ulcer awareness and prevention program: A quality improvement program through the Canadian Association of Wound Care. *Journal of Wound, Ostomy and Continence Nurses*, 36(2), 178–183; Dibsie, L. G. (2008). Implementing evidence-based practice to prevent skin breakdown. *Critical Care Nursing Quarterly*, 31(2), 140–149.

a back rub and whether gentle or deep massage is preferred. The patient's medical record should be reviewed for any contraindications to massage (e.g., fractured ribs, burns of the skin, or heart surgery). Box 37-10 examines the incidence and prevalence of pressure ulcers along with the associated costs and nursing implications.

Foot and Nail Care. Foot and nail care should be incorporated into a person's regular hygiene routine. Routine care involves soaking to soften the cuticles, thorough cleansing, drying, and proper nail trimming. The exception involves patients with diabetes mellitus, who do not soak their feet because of the risk of infection. When providing foot and nail care, patients may remain in bed or sit in a chair (Skill 37-2). In some settings or with specific patients, such as a person with diabetes mellitus, a physician's or nurse practitioner's order is needed to trim the toenails. Before implementing this procedure, check your agency's policy.

During the procedure, time is taken to teach the patients and family members the proper techniques for cleaning and nail trimming. Measures to prevent infection and promote good circulation should be stressed. Patients learn to protect

their feet from injury, keep their feet clean and dry, and wear footwear that fits properly. Patients are instructed on the proper way to inspect all surfaces of the feet and hands for lesions, dryness, and signs of infection. It is important for patients to recognize any abnormalities and the importance of reporting these conditions to their caregiver.

Patients with diabetes mellitus and/or peripheral vascular disease are at risk for the development of foot ulcers as a result of poor peripheral blood supply to the feet and decreased sensation in the feet. These lesions are slow to heal due to compromised circulation over time and can result in amputation (Senthuran, 2010). Appropriate patient teaching and daily foot care practices, along with early detection of diabetic foot ulcers, can decrease the risk of amputation (Canadian Diabetes Association, 2008).

Patients with diabetes mellitus or peripheral vascular disease should be provided information regarding how circulation directly affects the health and integrity of tissues of the feet and should be advised to use the following guidelines in a routine foot and nail care program:

- Inspect the feet daily, including the tops and soles of the feet, the heels, and the areas between the toes. Use a mirror to help inspect the feet thoroughly or ask a family member to check daily.
- If you have diabetes mellitus, you should receive a thorough foot examination at least once a year. If you have one or more high-risk foot conditions, you should be evaluated more frequently and referred to a specialist as necessary.
- Wash the feet daily using lukewarm water; *do not soak*. If you have reduced sensation, you may want to use a bath thermometer at home to test the water temperature. Thoroughly dry the feet and in between toes.
- Do not cut corns or calluses or use commercial removers. Consult a physician or podiatrist.
- If your feet perspire excessively, apply a nonallergenic foot powder.
- If dryness is noted along the sides of the feet, rub a nonallergenic lotion gently into the skin, wiping off any excess. *Do not apply lotion between the toes, as excessive moisture can result in infection.*
- Trim the toenails straight across and square; do not use scissors. Consult a podiatrist as needed.
- Do not use over-the-counter preparations or home remedies. Consult a physician or podiatrist.
- Constricting garments such as elastic stockings, knee-high hose, and garters and crossing the legs while sitting should be avoided as these can cause impaired circulation to the lower extremities.
- Wear clean, dry socks or stockings daily. Change socks twice a day if feet perspire heavily. Socks should be free of holes or repairs that might cause pressure on the tissue.
- Do not walk barefoot.
- Wear properly fitted shoes with porous uppers if possible. The soles of shoes should be flexible and nonslipping. Shoes should be sturdy, closed in, and not restrictive to the feet. New shoes should be worn for short periods of time over several days to break them in to avoid the formation of blisters. Patients with increased plantar pressure (e.g., due to erythema or callus) should use footwear that cushions and redistributes pressure. Patients with bony deformity (e.g., a bunion or Charcot's joint) may need extra-wide or extra-deep shoes with cushioned insoles.

► SKILL 37-2 Performing Nail and Foot Care

Delegation Considerations

The skill of nail and foot care for the nondiabetic patient can be delegated to a regulated or an unregulated care provider; however, this skill should not be delegated if the patient is diabetic. It is important to discuss the following:

- That nail clipping must be performed by you
- Any special considerations for patient positioning

Equipment

- Wash basin
- Emesis basin
- Washcloth and bath towel
- Nail clippers (the patient's)
- Emery board or nail file
- Unscented lotion
- Disposable bath mat
- Paper towels
- Disposable gloves

Procedure

STEPS

1. Identify patients at risk for foot or nail problems:
 - A. Older adult
 - B. Diabetes mellitus
 - C. Heart failure or renal disease
 - D. Cerebrovascular accident (stroke)
2. Assess patient's knowledge of foot and nail care practices.
3. Ask female patients about whether they use nail polish and polish remover frequently.
4. Assess patient's ability to care for nails or feet: consider visual alterations, fatigue, and musculoskeletal weakness.
5. Assess the types of home remedies (e.g., aloe vera, herbal preparations that the patient uses (Miller, 2009).
 - A. Over-the-counter chemical preparations to remove corns or calluses
 - B. Cutting or shaving of corns or calluses with razor blade or scissors
 - C. Use of oval corn pads
 - D. Application of adhesive tape
6. Assess the type of footwear worn by patients: Are socks worn? Are shoes tight or ill fitting? Are garters or knee-high nylons worn? Is footwear clean?
7. Observe patient's walking gait. Have the patient walk down a hall or in a straight line (if able).
8. Assist an ambulatory patient to sit in a bedside chair. Help a bed-bound patient to a supine position with head of the bed elevated. Place disposable bath mat on the floor under patient's feet or place a towel on the mattress.
9. Obtain a physician's or nurse practitioner's order for cutting nails if agency policy requires it.
10. Explain the procedure to the patient, including the fact that proper soaking requires several minutes.

RATIONALE

- Certain conditions increase the likelihood of foot or nail problems.
- Poor vision, lack of coordination, or inability to bend over contributes to difficulty in performing foot and nail care. Normal physiological changes of aging also result in nail and foot problems (MacDonald-Jenkins, 2009b).
- Vascular changes associated with diabetes mellitus reduce blood flow to peripheral tissues. Breaks in the skin integrity place a diabetic patient at high risk for a skin infection. Meticulous foot assessment and care reduce the diabetic patient's risk of debilitating foot problems (Senthuran, 2010).
- Both conditions can increase tissue edema, particularly in dependent areas (e.g., feet). Edema reduces blood flow to neighbouring tissues.
- The presence of residual foot or leg weakness or paralysis results in altered walking patterns. An altered gait pattern increases friction and pressure on feet.
- Determines patient's need for health teaching.
- Chemicals in these products can cause excessive dryness.
- Demonstrates patient's knowledge of proper foot care. Determines the amount of assistance and teaching required.
- Some preparations can cause injury to soft tissue (e.g., chemicals used to treat calluses) (Senthuran, 2010).
- Chemical preparations can cause burns and ulcerations.
- Cutting of corns or shaving calluses may result in a break in skin integrity and increases the risk for infection.
- Oval pads may exert pressure on the toes, thereby decreasing circulation to surrounding tissues.
- The skin of older adults is thin and delicate and prone to tearing when adhesive tape is removed.
- Types of shoes and footwear may predispose patient to foot and nail problems (e.g., infection, areas of friction, ulcerations). In patients with diabetes mellitus, nonhealing plantar ulcerations have been identified as one of the primary causes of lower limb amputation (Capes, 2007).
- Structural as well as painful disorders of the feet can cause limping or an unnatural gait.
- Sitting in a chair facilitates immersing feet in basin. The bath mat protects feet from exposure to soil or debris.
- The patient's skin may be accidentally cut. Certain patients are more at risk for infection, depending on their medical condition.
- Patient must be willing to place fingers and feet in basins for 10–20 minutes. Patient may become anxious or fatigued.

Critical Decision Point: Patients with diabetes do not soak hands and feet. Soaking increases their risk of infection due to maceration of the skin.

► SKILL 37-2 Performing Nail and Foot Care—cont'd

11. Perform hand hygiene. Arrange equipment on an overbed table.
 12. Fill wash basin with warm water. Test water temperature.
 13. Place basin on bath mat or towel.
 14. Fill emesis basin with warm water, and place basin on paper towels on overbed table.
 15. Pull curtain around the bed or close the room door (if desired).
 16. Inspect all surfaces of the fingers, toes, feet, and nails. Pay particular attention to areas of dryness, inflammation, or cracking. Also inspect the areas between toes, heels, and soles of feet.
- Reduces transmission of microorganisms. Easy access to equipment prevents delays.
 - Warm water softens nails and thickened epidermal cells, reduces inflammation of the skin, and promotes local circulation. Proper water temperature prevents burns.
 - Avoids spills; this maintains the safety of the care provider and the patient.
 - Warm water softens nails and thickened epidermal cells.
 - Maintaining the patient's privacy reduces anxiety.
 - The integrity of feet and nails determines the frequency and level of hygiene required. Heels, soles, and sides of the feet are prone to irritation from ill-fitting shoes.

Critical Decision Point: Patients with peripheral vascular diseases or diabetes mellitus, older adults, and patients whose immune system is suppressed may require nail care from a specialist to reduce the risk of infection.

17. Assess the colour and temperature of toes, feet, and fingers. Assess capillary refill. Palpate radial and ulnar pulses of each hand and dorsalis pedis pulses of feet (see Chapter 31).
 18. Instruct patient to place his or her fingers in the emesis basin and place arms in a comfortable position. Assist the patient to place feet in the basin.
 19. Allow patient's feet and fingernails to soak for 10–20 minutes (unless the patient has diabetes). Rewarm the water after 10 minutes.
 20. Clean gently under the fingernails with an orange stick or the wooden end of a cotton-tipped swab while fingers are immersed (see Step 20 illustration). Remove fingers from the emesis basin, and dry thoroughly.
 21. Using nail clippers, clip fingernails straight across and even with the tops of fingers (see Step 21 illustration). Using a file, shape the nails straight across. If patient has circulatory problems, do not cut the nail; only file the nail.
- Assesses the adequacy of blood flow to extremities. Peripheral vascular disease can contribute to poor wound healing. Patients who are immunocompromised or who have neuropathy or peripheral vascular disease are at an increased risk of foot infections (Senthuran, 2010).
 - Prolonged positioning can cause discomfort unless normal anatomical alignment is maintained.
 - Patients with muscular weakness may have difficulty positioning their feet.
 - Softening of corns, calluses, and cuticles ensures easy removal of dead cells and easy manipulation of cuticles.
 - The orange stick removes debris under nails that harbours microorganisms. Thorough drying impedes fungal growth and prevents maceration of the tissues.
 - For infection-control purposes, use the patient's own nail clippers. Cutting straight across prevents splitting of the nail margins and the formation of sharp nail spikes that can irritate lateral nail margins. Filing prevents cutting the nail too close to the nail bed.

Step 20 Clean fingernails with the end of a cotton-tipped swab or an orange stick.

22. Push cuticle back gently with a wet facecloth. Thoroughly dry the hands.
23. Move the overbed table away from the patient.
24. Put on disposable gloves, and scrub callused areas of the feet with a washcloth.

Step 21 Using nail clippers, trim nails straight across.

- Reduces incidence of inflamed cuticles. Thorough drying impedes fungal growth and prevents maceration of the tissues.
- Provides easier access to the feet.
- Gloves prevent the transmission of fungal infection. Friction removes dead skin layers.

Continued

► SKILL 37-2 Performing Nail and Foot Care—cont'd

25. Clean gently under nails with an orange stick. Remove feet from basin, and dry them thoroughly.
 26. Clean and trim the toenails using the procedures in Steps 21 and 22. Do not file the corners of toenails.
 27. Apply lotion to feet and hands, and assist patient back to bed and into a comfortable position.
 28. Remove disposable gloves and place in a receptacle. Clean and return the equipment and supplies to the proper place. Dispose of soiled linen in a hamper. Perform hand hygiene.
 29. Inspect the nails and surrounding skin surfaces after soaking and nail trimming.
 30. Ask patient to explain or demonstrate nail care.
 31. Observe patient's walk after toenail care.
- Removal of debris and excess moisture reduces chances of infection.
 - For infection control purposes, use the patient's own nail clippers. Shaping corners of toenails may damage tissues.
 - Lotion lubricates dry skin by helping to retain moisture.
 - Reduces the transmission of infection.
 - Determines the condition of skin and nails. Allows you to note any remaining rough nail edges.
 - Evaluates patient's level of learning techniques.
 - Evaluates the level of comfort and mobility achieved.

Unexpected Outcomes

Inflammation and tenderness of cuticles and surrounding tissues

Localized areas of tenderness on feet, with calluses or corns at points of friction

Appearance of ulcer between toes or other pressure areas in foot

Related Interventions

- Repeated soakings may be needed to relieve inflammation and loosen layers of cells from calluses or corns.
- Patient with diabetes or peripheral vascular disease may require referral to a podiatrist.
- Antifungal cream may be needed.
- Change in footwear may be needed.
- Refer to a podiatrist.
- Notify physician.
- Refer to a podiatrist.
- Increase frequency of foot assessment and hygiene.

Recording and Reporting

- Document the procedure and any observations (e.g., breaks in the skin, inflammation, ulcerations) on the patient's record sheets using the forms provided by your agency or facility.
- Report any breaks in the skin or ulcerations to the person in charge or the physician. These breaks are serious in patients with diabetes, peripheral vascular disease, and illnesses that impair circulation. Special foot care treatments may be needed.

Home Care Considerations

- If the patient has diabetes or decreased peripheral circulation, alternative therapies or foot soaking should be done only after consulting with a physician.
- An alternative therapy would be moleskin applied to areas of the feet that are experiencing friction—this is less likely to cause pressure than corn pads. Spot adhesive bandages can guard against friction, but they do not have padding to protect against pressure.
- If the patient is ambulatory, instruct him or her to soak feet in a bathtub.
- If the patient's mobility is limited, a large basin or pan can be used for soaking.

- Do not wear high-heeled, open-toed, or pointed-toe shoes.
- Exercise regularly to improve circulation to the lower extremities. Walk slowly and elevate, rotate, flex, and extend the feet at the ankles. Dangle the feet over the side of the bed for one minute, then extend both legs and hold them parallel to the bed while lying supine for one minute, and, finally, rest for one minute.
- Do not apply hot water bottles or heating pads directly to the feet.
- Wash minor cuts immediately and dry them thoroughly. Use only mild antiseptics (e.g., Neosporin ointment). Contact a physician or nurse practitioner to treat cuts or lacerations (Senthuran, 2010, p. 1344; Canadian Diabetes Association, 2008; Capes, 2007).

Any patients who require regular, thorough foot care should have a caregiver or family member able to provide care during times when the patient is incapacitated. Patients with visual difficulties, physical constraints preventing movement, or cognitive problems that impair their ability to assess the condition of the feet need caregiver or family assistance.

Oral Hygiene

Oral hygiene helps to maintain the healthy state of the mouth, teeth, gums, lips, and tongue (Canadian Dental Association, 2005). Brushing cleans the teeth of food particles, plaque, and bacteria. It also massages the gums and relieves any discomfort resulting from unpleasant odours and tastes. Flossing helps to further remove plaque and bacteria from between the teeth to reduce gum inflammation and infection. Complete oral hygiene enhances well-being and comfort and stimulates the appetite.

Patients also benefit from a diet that excludes foods that promote plaque formation and tooth decay and that promotes healthy periodontal structures (Canadian Dental Association, 2005). Plaque-forming foods include carbonated beverages, breads, and starches. Oral hygiene immediately after a meal further reduces plaque. You can assist patients in maintaining good oral hygiene by teaching them the importance of correct techniques and a routine daily schedule.

Patients of all ages should be advised to have a dental checkup at least every six months. Education about common

* BOX 37-11 FOCUS ON OLDER ADULTS

- Many older adults are edentulous (without teeth), and the teeth that are present are often diseased or decayed (Meiner & Lueckenotte, 2006).
- The periodontal membrane weakens, making it more prone to infection; periodontal disease can predispose older adults to systemic infection.
- The presence of chronic illnesses (e.g., diabetes mellitus, renal insufficiency, and cardiovascular diseases) increases older adults' risk for periodontal disease (Estes & Buck, 2008; Miller, 2009).
- Dentures or partial plates may not fit properly, causing pain and discomfort; this can, in turn, affect digestive processes, the enjoyment of food, and nutritional status (Ebersole et al., 2008).
- Weaker jaw muscles and shrinkage of the bony structure of the mouth may increase the work of chewing and lead to increased fatigue when eating (Meiner & Lueckenotte, 2006).
- Dry mouth can be caused by an age-related decline in saliva secretion, as well as by over 400 medications that are frequently used by older adults (Miller, 2009; Wilson-Keates, 2009).
- Poor nutritional status in some older adults can increase the risk for and severity of dental problems (e.g., caries, periodontal disease, receding gums, and tooth degeneration) (Miller, 2009).
- An inability or unwillingness to access dental care and the belief that tooth loss is a natural outcome of aging are reasons why some older adults do not seek dental care (Ebersole et al., 2008).
- Financial limitations, low income, and lack of transportation also contribute to inadequate dental care of some older adults (Miller, 2009).

gum and tooth disorders and methods of prevention can motivate patients to follow good oral hygiene practices. Provide assistance with oral hygiene for weakened or disabled patients. When patients have variations in oral mucosal integrity, adapt hygiene techniques to ensure thorough and effective care (Box 37-11).

Brushing and Flossing. Thorough tooth brushing at least four times a day (after meals and at bedtime) is basic to an effective oral hygiene program. If patients are unable to perform oral care four times per day, they should do it at least once during the day and always at night. All tooth surfaces should be brushed thoroughly with a fluoride toothpaste. A toothbrush should have a straight handle and a brush small enough to reach all areas of the mouth. A toothbrush with soft, rounded bristles should be used to stimulate gums without causing bleeding. Toothbrushes should be replaced every three months (Canadian Dental Association, 2005). Older adult patients with reduced dexterity and grip may require an enlarged handle with an easier grip or an electric toothbrush (Miller, 2009). One simple way to make an enlarged brush handle is to pierce a soft rubber ball and push the brush handle through it or glue a short piece of plastic tubing around the handle. Commercially made foam rubber toothbrushes are useful for patients with sensitive gums. However, swabbing fails to cleanse teeth adequately because plaque accumulates around the base of the teeth. Foam rubber swabs should be used in moderation. Electric toothbrushes can be used, but consult your agency's policy to ascertain whether their use is permitted. Lemon-glycerine sponges should not be used because they dry mucous membranes and erode teeth enamel. Moi-Stir is a salivary supplement that improves moisture and the texture of the tongue and mucosa (Miller, 2009).

When teaching patients about mouth care, you should recommend that they do not share toothbrushes with family members or drink directly from a bottle of mouthwash. Cross-contamination occurs easily. The use of disclosure tablets or drops to stain the plaque that collects at the gum line can be useful for showing patients how effectively they brush.

Patients experience conditions that threaten the integrity of the oral mucosa. For example, mucosal changes associated with aging, use of chemotherapeutic drugs, or dehydration require a change in oral hygiene. More frequent mouth care and use of anti-infective agents are examples of ways you can revise approaches to meet patient needs. Unconscious patients and those with artificial airways (e.g., endotracheal or tracheal tubes) need more frequent and specialized oral hygiene. These patients have an increased risk of aspiration and, subsequently, aspiration pneumonia, and they also have more problems with dry and inflamed oral mucosa.

The amount of assistance needed by the patient when brushing the teeth may vary. Many patients can perform their own oral care and should be encouraged to do so. You should observe patients to be sure proper techniques are used. When assisting with or providing oral hygiene, you must determine the amount of assistance needed and the individuals' oral hygiene preferences (Skill 37-3).

Flossing. Dental flossing removes plaque and bacteria from between teeth. Flossing involves inserting waxed or unwaxed dental floss between all tooth surfaces, one space at a time. Flossing at least once a day is sufficient (Canadian Dental Association, 2005). To prevent bleeding, patients who are receiving chemotherapy or radiation or who are on anticoagulant therapy should use unwaxed floss and avoid vigorous flossing near the gum line. If toothpaste is applied to the teeth before flossing, this allows fluoride to come in direct contact with tooth surfaces, aiding in cavity prevention. Because it is important to clean all tooth surfaces thoroughly, you should not rush flossing. Placing a mirror in front of the patient helps you to demonstrate the proper method for holding the floss and cleaning between the teeth. Flossing a patient's teeth is not realistic or appropriate in all care settings. However, flossing may be done more frequently in rehabilitation and long-term care settings.

Patients With Special Needs. Some patients require special oral hygiene methods because of their level of dependence on the care provider or the presence of oral mucosa problems. Unconscious patients are susceptible to drying of mucous-thickened salivary secretions because they are unable to eat or drink, frequently breathe through the mouth, and often receive oxygen therapy. Unconscious patients also cannot swallow salivary secretions that accumulate in the mouth. These secretions often contain Gram-negative bacteria that can cause pneumonia if aspirated into the lungs. While providing hygiene to unconscious patients, you must protect them from choking and aspiration. While cleansing the oral cavity, you should never use your fingers to hold the patient's mouth open as a human bite is highly contaminated. It may be necessary to perform mouth care at least every two hours for the unconscious patient. Research shows that the use of chlorhexidine with oral hygiene reduces the risk of ventilator-associated pneumonia (Berry et al., 2007; Munro et al., 2006). Explain the steps of mouth care and the sensations the patient will feel, and advise the patient when the procedure is completed (Skill 37-4).

Text continued on p. 860

► SKILL 37-3 Providing Oral Hygiene

Delegation Considerations

The skill of oral hygiene can be delegated to an unregulated care provider (UCP). It is important to discuss the following with the UCP:

- How to adapt the procedure for a patient who is at risk of aspiration. (e.g., those with an impaired level of consciousness or impaired swallowing, and those who are confused).
- To immediately report excessive patient coughing or choking during or after oral hygiene
- To report any bleeding of the oral mucosa or gums, lesions, or patient report of pain
- To report any concerns with dentures (e.g., ill-fitting or broken dentures)

Procedure

STEPS

1. Determine patient's oral hygiene practices:
 - A. Frequency of tooth brushing and flossing
 - B. Type of toothpaste or dentifrice used
 - C. Last dental visit
 - D. Frequency of dental visits
 - E. Type of mouthwash or moistening preparation such as over-the-counter saliva substitutes or sugar-free gum with xylitol (Miller, 2009).
2. Assess risk for oral hygiene problems (see Table 37-5).
3. Assess patient's risk for aspiration: impaired swallowing, reduced gag reflex.
4. Assess patient's ability to grasp and manipulate a toothbrush. (For older adults, try a 30-second tooth brushing assessment.)
5. Prepare equipment at bedside.
6. Perform hand hygiene and put on disposable gloves.
7. Inspect the integrity of the lips, teeth, buccal mucosa, gums, palate, and tongue (see Chapter 31).
8. Identify the presence of common oral problems:
 - A. Dental caries—chalky white discolouration of a tooth or the presence of brown or black discolouration
 - B. Gingivitis—inflammation of gums
 - C. Periodontitis—receding gum lines, inflammation, gaps between teeth
 - D. Halitosis—bad breath
 - E. Cheilosis—cracking of the lips
 - F. Stomatitis—inflammation of the oral tissues
 - G. Dry, cracked, coated tongue
9. Explain the procedure to the patient and discuss preferences regarding the use of hygiene aids.
10. Raise the bed to a comfortable working position. Raise head of the bed (if patient's condition allows) and lower the side rail. Move the patient, or help patient move closer. A side-lying position can be used.
11. Place paper towels on an overbed table, and arrange other equipment within easy reach.
12. Place a towel over patient's chest.
13. Apply toothpaste to brush, holding brush over the emesis basin. Pour a small amount of water over toothpaste.

Equipment

- Soft-bristled toothbrush
- Nonabrasive fluoride toothpaste or dentifrice
- Dental floss
- Water glass with cool water
- Normal saline or an essential oil antiseptic mouthwash (optional; follow patient's preference)
- Emesis basin
- Tongue blade
- Face towel
- Paper towels
- Disposable gloves

RATIONALE

- Allows you to identify errors in technique, deficiencies in preventive oral hygiene, and patient's level of knowledge regarding dental care.
- Mouthwash provides a pleasant aftertaste but can dry mucosa after extended use if it has an alcohol base.
- Certain conditions increase the likelihood of impaired oral cavity integrity and the need for preventive care.
- An accumulation of secretions and dentifrice can increase the patient's risk for aspiration if the patient's ability to control oral secretions is impaired.
- A toothbrush test is useful in assessing dexterity and strength. Determines level of assistance required.
- Avoids interrupting the procedure or leaving the patient unattended to retrieve missing equipment.
- Reduces the transmission of microorganisms.
- Determines status of patient's oral cavity and the extent of need for oral hygiene.
- Helps determine type of hygiene patient requires and information patient requires for self-care.
- Receding gums can occur with aging, and as a result older patients require meticulous oral hygiene.
- Patients receiving immunosuppressive chemotherapy (e.g., cancer chemotherapy) and patients with suppressed immune function are at risk for stomatitis (Cummings-Winfield & Olson, 2010).
- Some patients feel uncomfortable about having you care for their basic needs. Patient involvement with procedure minimizes anxiety.
- Raising the bed and repositioning the patient prevents straining of muscles. A semi-Fowler position helps prevent patient from choking or aspirating.
- Prevents soiling of the tabletop. Equipment prepared in advance ensures a smooth, safe procedure.
- Prevents soiling of bed linen and patient's clothing.
- Moisture aids in the distribution of toothpaste over tooth surfaces.

► SKILL 37-3 Providing Oral Hygiene—cont'd

14. Patient may assist by brushing. Hold toothbrush bristles at 45-degree angle to gum line (see Step 14 illustration, part A). Be sure tips of bristles rest against and penetrate under gum line. Brush inner and outer surfaces of upper and lower teeth by brushing from gum to crown of each tooth. Clean biting surfaces of teeth by holding top of bristles parallel with teeth and brushing gently back and forth (see Step 14 illustration, part B). Brush sides of teeth by moving bristles back and forth (see Step 14 illustration, part C).
15. Have patient hold brush at 45-degree angle and lightly brush over surface and sides of tongue (see Step 15 illustration). Avoid initiating gag reflex.

Step 14 Direction for toothbrush placement. A, A 45-degree angle brushes gum line. B, Parallel position brushes biting surfaces. C, Lateral position brushes sides of teeth.

16. Allow patient to rinse mouth thoroughly by taking several sips of water, swishing water across all tooth surfaces, and spitting into the emesis basin.
17. Allow patient to gargle and rinse mouth with mouthwash as desired.
18. Assist in wiping patient's mouth.
19. Allow patient to floss.
20. Allow patient to rinse mouth thoroughly with cool water and spit into emesis basin. Assist in wiping patient's mouth.
21. Ask patient whether any area of oral cavity feels uncomfortable or irritated. Inspect the oral cavity.
22. Assist patient to comfortable position, remove emesis basin and bedside table, raise side rail, and lower the bed to the original position.
23. Wipe off overbed table, discard soiled linen and paper towels in appropriate containers, remove soiled gloves, and return equipment to the proper place.
24. Remove gloves and perform hand hygiene.
25. Ask patient to describe proper hygiene techniques.

Unexpected Outcomes

Dryness and inflammation of oral mucosa

Retraction of gum margins from teeth, localized areas of inflammation, and bleeding around gum margins

Signs of dental caries

- Angle allows brush to reach all tooth surfaces and to clean under gum line where plaque and bacteria accumulate. Back-and-forth motion dislodges food particles caught between teeth and along chewing surfaces.
- Microorganisms collect and grow on tongue's surface and contribute to bad breath. Gagging may cause aspiration of toothpaste. Evaluates patient's ability to use correct technique.

Step 15 Assisting patient with brushing tongue.

- Irrigation removes food particles.
- Mouthwash can be effective in reducing plaque and gingivitis (Werner & Seymour, 2009).
- Promotes sense of comfort.
- Reduces tartar between tooth surfaces.
- Irrigation removes plaque and tartar from the oral cavity.
- Pain can indicate a problem.
- Provides for patient comfort and safety.
- Proper disposal of soiled equipment prevents the spread of microorganisms.
- Reduces the transmission of microorganisms.
- Evaluates patient's learning.

Related Interventions

- Increase frequency of oral hygiene.
- Increase patient's hydration (if permitted).
- Apply water-soluble lubricant to the patient's lips.
- Determine whether patient has an underlying bleeding tendency (e.g., anticoagulant therapy).
- Report findings to the physician or person in charge.
- Use a soft-bristled toothbrush.
- Increase frequency of oral hygiene.
- Refer patient to a dentist.
- Teach patient oral hygiene techniques.

Continued

► SKILL 37-3 Providing Oral Hygiene—cont'd

Recording and Reporting

- Record all procedures on a flow sheet provided by your agency or facility. Note the condition of the oral cavity in the patient care notes.
- Report any bleeding or the presence of lesions to the person in charge or the physician.

Home Care Considerations

- Teach the patient and caregiver to assess the oral cavity daily to determine any effects of medications on the oral cavity (e.g., reddened, inflamed gums).

► SKILL 37-4 Performing Mouth Care for an Unconscious or Debilitated Patient

Delegation Considerations

Oral hygiene of an unconscious or debilitated patient can be delegated to an unregulated care provider (UCP). You must first assess the patient for the gag reflex and determine whether the person providing assistance can safely use oral suctioning for clearing the patient's oral secretions (see Chapter 38). When delegating tasks to a UCP, it is important to instruct him or her about the following:

- The proper way to position the patient for mouth care
- How to safely use oral suctioning for clearing oral secretions (see Chapter 38)
- To report to any bleeding of the mucosa or gums, any painful reaction by the patient, or excessive coughing or choking

Equipment

- Antiseptic oral rinse (e.g., chlorhexidine gluconate [Peridex])
- Small soft-bristled toothbrush
- Sponge swab (e.g., Toothette swab) or tongue blade wrapped in a single layer of gauze
- Oral airway
- Padded tongue blade
- Face towel
- Paper towels
- Emesis basin
- Water glass with cool water
- Water-soluble lip lubricant
- Small-bulb syringe (optional)
- Suction equipment
- Disposable gloves

Procedure

STEPS

1. Assess patient's risk for oral hygiene problems (see Table 37-5).
2. Explain procedure to patient.
3. Test for the presence of a gag reflex by touching the posterior pharyngeal wall with a tongue blade.

RATIONALE

- Oral care is provided frequently to intubated patients who also have a nasogastric tube and who are at risk of aspiration, which can lead to pneumonia (Ross, 2010).
- Allows debilitated patient to anticipate procedure without anxiety. Unconscious patients retain ability to hear.
- Reveals whether patient is at risk for aspiration.

Critical Decision Point: Patients with an impaired gag reflex require oral care as well. You must determine the type of suction apparatus needed at the bedside to protect the patient's airway against aspiration.

4. Raise bed to the appropriate height; lower head of the bed (if patient's condition permits) and then lower the side rail.
 5. Pull curtain around the bed, or close the room door.
 6. Perform hand hygiene and put on disposable gloves.
 7. Place paper towels on an overbed table and arrange equipment. If needed, turn on a suction machine and connect tubing to the suction catheter.
 8. Position patient on side (Sims' position) with head turned well toward dependent side. Move patient close to side of the bed. Raise the side rail.
 9. Place a towel under patient's head and an emesis basin under the chin.
 10. Carefully separate upper and lower teeth with padded tongue blade by inserting blade, quickly but gently, between back molars. Insert blade when patient is relaxed, if possible. Do not use force (see Step 10 illustration).
- Allows use of good body mechanics and reduces the risk of injury.
 - Provides privacy.
 - Reduces the transfer of microorganisms. Gloves prevent contact with microorganisms in blood or saliva.
 - Prevents soiling of the tabletop. Equipment prepared in advance ensures a smooth, safe procedure.
 - Turning the patient's head to the side allows secretions to drain from mouth instead of collecting in the back of the pharynx. Prevents aspiration. Moving the patient close to the side of the bed facilitates proper body mechanics.
 - Prevents soiling of bed linen and patient's gown.
 - Prevents patient from biting down on your fingers and provides access to oral cavity.

Critical Decision Point: Never use fingers to separate the patient's teeth.

► SKILL 37-4 Performing Mouth Care for an Unconscious or Debililitated Patient—cont'd

11. Inspect condition of the oral cavity (see Chapter 31).
12. Clean mouth using brush or sponge Toothette swabs moistened with chlorhexidine solution if patient condition can tolerate it; otherwise, moisten with water. Clean chewing and inner and outer tooth surfaces. Swab roof of mouth, gums, and inside cheeks. Gently swab or brush tongue, but avoid stimulating gag reflex (if present). Moisten clean swab or Toothette swab with water to rinse. (Bulb syringe may also be used to rinse.) Repeat rinse several times.
13. Suction secretions as they accumulate, if necessary.
14. Apply a thin layer of water-soluble lubricant to lips (see Step 14 illustration).

Step 10 Separate upper and lower teeth with padded tongue blade.

15. Inform patient that procedure is completed.
16. Put on clean gloves, and inspect oral cavity.
17. Ask debilitated patient whether mouth feels clean.
18. Reposition patient comfortably, raise side rail as appropriate or as ordered, and return the bed to original position.
19. Clean equipment and return to its proper place. Place soiled linen in the proper receptacle.
20. Remove and discard gloves. Perform hand hygiene.
21. Assess patient's respirations on an ongoing basis.

Unexpected Outcomes

Secretions or crusts remaining on oral mucosa, tongue, or gums

Localized inflammation of gums or mucosa

Aspiration of secretions

- Determines condition of the oral cavity and the need for hygiene.
- Brushing action removes food particles between teeth and along chewing surfaces. Swabbing helps remove secretions and crusts from mucosa and moistens mucosa. Rinsing removes any debris and cleansing agent, and provides for patient comfort.
- Suction removes secretions and fluid that can collect in the posterior pharynx.
- Lubricates lips to prevent drying and cracking.

Step 14 Application of water-soluble moisturizer to lips.

- Provides meaningful stimulation to unconscious or less responsive patient.
- Determines efficacy of cleansing. Once thick secretions are removed, underlying inflammation or lesions may be revealed.
- Evaluates level of comfort.
- Maintains patient's comfort and safety. Raising all four side rails may be considered a restraint, and a physician's order is needed.
- Proper disposal of soiled equipment prevents the spread of microorganisms.
- Reduces the transmission of microorganisms.
- Ensures early recognition of aspiration.

Related Interventions

- Increase frequency of oral hygiene.
- Try using a pediatric-size toothbrush—it may provide better hygiene if the oral cavity is difficult to access.
- Increase frequency of oral hygiene with a soft-bristled toothbrush.
- Apply moisturizing gel on the oral mucosa.
- Chemotherapy and radiation can cause stomatitis. To provide relief and promote oral hygiene, topical anti-inflammatories and anaesthetics may be prescribed (Cummings-Winfield & Olson, 2010).
- Suction oral airway.
- Perform tracheal bronchial suctioning.
- Notify the physician.

Continued

► SKILL 37-4 Performing Mouth Care for an Unconscious or Debilitated Patient—cont'd

Recording and Reporting

- Record the procedure, including pertinent observations (e.g., the presence of bleeding gums, dry mucosa, ulcerations, or crusts on the tongue).
- Report any unusual findings to the person in charge or the physician.

Home Care Considerations

- Cavity should be irrigated with bulb syringe.
- Mouth care should be given at least twice a day. Caregivers can buy nonprescription oral care solutions (e.g., chlorhexidine solutions) at most pharmacies.
- Have caregivers demonstrate positioning of the patient to prevent aspiration.

► BOX 37-12 Procedural Guideline

Care of Dentures

Delegation Considerations:

The skill of denture care can be delegated to an unregulated care provider (UCP). It is important to discuss the following with the UCP:

- To report any cracks found in the dentures
- To report any patient complaints of oral discomfort
- To report any signs of irritation, inflammation, or lesions

Equipment:

- Soft-bristled toothbrush or denture toothbrush
- Denture cleaning agent or toothpaste
- Denture adhesive (optional)
- Glass of water
- Emesis basin or sink
- Washcloth
- Disposable gloves
- Denture cup (if dentures are to be stored after cleaning)

Procedure:

1. Ask patient whether dentures fit and whether the gums or mucous membranes are tender or irritated.
2. Ask patient about preferences for denture care and products used. If patient is unable to care for own dentures, you must provide this care. Clean dentures for the patient during routine mouth care.
3. Fill emesis basin with tepid water or, if using sink, place washcloth in bottom of sink and fill sink with 2.5 cm of water.
4. Remove dentures. If patient is unable to do this independently, perform hand hygiene and put on gloves, grasp upper plate at front with thumb and index finger wrapped in gauze, and pull downward. Gently lift lower denture from jaw, and rotate one side downward to remove from patient's mouth. Place dentures in emesis basin or sink.

5. Apply cleaning agent to brush and brush surfaces of dentures (see Step 5 illustration). Hold dentures close to water. Hold the brush horizontally, and use a back-and-forth motion to cleanse biting surfaces. Use short strokes from the top of the denture to biting surfaces to clean outer and inner teeth surfaces. Hold the brush vertically, and use short strokes to clean inner tooth surfaces. Hold the brush horizontally, and use a back-and-forth motion to clean the undersurface of dentures.

Step 5 Brushing dentures.

6. Rinse thoroughly in tepid water.
7. Some patients use an adhesive to seal dentures in place. If so, apply a thin layer to the undersurface before inserting.
8. If patient needs assistance with the insertion of dentures, moisten the upper denture and press firmly to seal it in place. Then insert moistened lower denture. Ask whether dentures feel comfortable.
9. Dentures should be removed at night and the gums cleaned gently. Dentures should be stored in a denture container that is labelled with the patient's name and placed in the bedside table to prevent loss.
10. Remove and discard gloves and perform hand hygiene.

Patients who receive chemotherapy, radiation, or nasogastric tube intubation or who have an infection of the mouth can suffer from stomatitis, an inflammation of the oral mucosa that can cause burning, pain, and a change in food tolerance. Gentle brushing and flossing are important in preventing bleeding of the gums. Patients should be advised to avoid alcohol and commercial mouthwash and to stop smoking. Normal saline rinses (approximately 30 mL) used upon awaking in the morning, after each meal, and at bedtime can effectively clean the oral cavity. The rinses can be increased to every two hours, if necessary. The physician or nurse practitioner may order a mild oral analgesic for pain control.

Patients with diabetes mellitus frequently have periodontal disease and should have regular, yearly (or more frequently if necessary) visits to the dental professional for oral health assessment and care. All tissues should be handled gently with a minimum of trauma. Patients should learn to follow rigid cleansing schedules, at least four times a day.

Denture Care. Patients should be encouraged to clean their dentures on a regular basis to avoid gingival infection and irritation. When patients become disabled, the care provider or family caregiver can assume responsibility for denture care (Box 37-12). Dentures are patients' personal property and need to be handled with care because they can be easily broken.

They must be removed at night to give the gums a rest and prevent bacterial buildup. Dentures should be kept covered in water when they are not worn to prevent warping, and they should always be stored in an enclosed, labelled cup and placed in a patient's bedside stand. Discourage patients from removing dentures and placing them on a napkin or tissue because they could be easily thrown away.

Hair and Scalp Care

A person's appearance and feeling of well-being can often depend on the way his or her hair looks and feels. Illness or disability may prevent patients from maintaining daily hair care. Immobilized patients' hair soon becomes tangled. Dressings may leave sticky blood or antiseptic solutions on the hair. In the clinic and home care setting, you may encounter patients who have head lice. Proper hair care is important to patients' body image. Brushing, combing, and shampooing are basic hair hygiene measures for all patients.

Brushing and Combing. Frequent brushing and combing helps to keep hair clean and distributes oil evenly along hair shafts and prevents hair from tangling. Patients should be encouraged to maintain routine hair care. However, patients with limited mobility or weakness and those who are confused require assistance. Patients in a hospital or long-term care facility appreciate the opportunity to have their hair brushed and combed before being seen by others.

When caring for patients from different cultures, it is important to learn as much as possible from them or their family about their preferred hair care practices. Cultural preferences affect how hair is combed and styled.

Long hair can easily become matted when patients are confined to bed, even for a short period. When lacerations or incisions involve the scalp, blood and topical medications can also cause tangling. Frequent brushing and combing keeps long hair neatly groomed. Braiding can help to avoid repeated tangles; however, braids should be unbraided periodically and the hair combed to ensure good hygiene. Braids made too tightly can result in bald patches. Always obtain permission from the patients, if conscious, before braiding their hair.

To brush the hair, part it into two sections and separate each into two more sections. It is easier to brush smaller sections of hair. Brushing from the scalp toward the hair ends minimizes pulling. Moistening the hair with water frees tangles for easier combing. Never cut a patient's hair without verbal or written consent if they are cognitive and able to give consent.

Patients who develop head lice require special considerations in the way combing is performed. The lice are small, about the size of a sesame seed. Bright light or natural sunlight is necessary for the lice to be seen. Thorough combing is recommended and may remove nits (empty eggshells) if infestation is extensive. Follow these steps:

- Put on a disposable gown and gloves.
- Use a grooming comb or hairbrush to remove any tangles.
- Divide the patient's hair in sections and fasten off the hair that is not being combed.
- Comb out from the scalp to the end of the hair (special fine-tooth combs are available in drugstores).
- Between each pass, dip the comb in a cup of water or use a paper towel to remove nits.
- After combing, look through the hair carefully for attached live lice.
- Catch live lice with tweezers or comb.
- Move to next section of hair after combing thoroughly.

- Instruct the family to clean the comb with an old toothbrush and dental floss and boil the comb (if possible). The ideal would be to discard the comb after each use, but some patients' financial situations may prevent the purchase of multiple combs.
- Instruct the family to comb and screen for lice daily.
- Instruct the family to contain the patient's clothes and then wash them in hot water.
- Instruct caregivers on how to prevent the transmission of lice:
 - Do not share bed linens.
 - Avoid placing your bare hand on patient's head.
 - Immediately wash your hands after providing hair care.
 - Contain all hair care products.

If a pediculicidal shampoo is ordered, instruct the patient and caregiver on the proper use of shampoo. Lindane, an organochloride, can have neurological side effects. Shampoos containing lindane are contraindicated for those patients under 50 kg, neonates, those who take medications that lower seizure threshold (e.g., tricyclic antidepressants), and patients who have human immunodeficiency virus (HIV) (Brophy et al., 2008; Frankowski et al., 2010). As with any medication preparation, it is important to review and understand the product information provided in the packaging.

Shampooing. To best promote and restore hair and scalp health, patients should be instructed to keep hair clean, combed, and brushed regularly. Patients may also need to know how to check for and remove parasites, such as lice (see Table 37-4). You should inform patients that they need to notify their primary caregiver of changes in the texture and distribution of hair, which may indicate a serious systemic problem.

Frequency of shampooing depends on patients' daily routines and the condition of their hair. You should remind patients in hospitals or long-term care facilities that staying in bed, perspiring excessively, or undergoing treatments that leave blood or solutions in the hair may result in a need for more frequent shampooing.

For patients at home who have limited mobility, it is challenging to find ways that they can shampoo their hair without causing injury. If patients are able to take a shower or bath, their hair can usually be shampooed without difficulty. A shower or tub chair may be used for ambulatory, weight-bearing patients who become fatigued or faint. Hand-held shower nozzles allow patients to easily wash their hair in the tub or shower. Patients allowed to sit in a chair may choose to be shampooed in front of a sink or over a wash basin. However, bending is limited or contraindicated in certain conditions (e.g., eye surgery or neck injury). In these situations, you need to teach the patients and their family members the degree of bending allowed.

If patients are unable to sit but can be moved, you may transfer them to a stretcher for transportation to a sink or shower equipped with a hand-held nozzle. This equipment is commonly found in long-term care facilities. Caution is again needed when the patients' head and neck are positioned, particularly in patients with any form of head or neck injury.

If patients are unable to sit in a chair or be transferred to a stretcher, shampooing must be done while the patients are in bed (Box 37-13). A special shampoo trough can be positioned under the patient's head to catch water and suds. After shampooing, patients like having their hair styled and dried. Dry shampoos that reduce the need to wet the patients' hair are also available but are not highly effective. These dry shampoos

video

Shampooing the Hair of a Bed-Bound Patient**Delegation Considerations:**

The skill of shampooing hair can be delegated to an unregulated care provider (UCP). It is important to discuss the following with the UCP:

- To follow any precautions necessary in positioning the patient
- To report any patient complaints of neck pain
- To report condition of the scalp and hair

Equipment:

- Bath towels
- Washcloths
- Shampoo
- Hair conditioner (if available)
- Water pitcher with warm water
- Plastic shampoo trough
- Wash basin
- Bath blanket
- Waterproof pad
- Clean comb and brush
- Hair dryer (if warranted by patient's condition)
- Disposable gloves (optional)

Procedure:

1. Before washing the patient's hair, ensure that this procedure is not contraindicated for the patient. Certain medical conditions, such as head and neck injuries, spinal cord injuries, and arthritis, could place the patient at risk for injury during shampooing because of positioning and manipulation of the patient's head and neck.
2. Put on gloves if needed. Inspect the hair and scalp before initiating the procedure to determine the presence of any conditions that may require the use of special shampoos or treatments (e.g., for dandruff or the removal of dried blood).
3. Place waterproof pad under patient's shoulders, neck, and head (see Step 3 illustration). Position patient supine, with head and shoulders at top edge of the bed. Place a plastic trough under patient's head and a wash basin at end of trough. Be sure the trough spout extends beyond the edge of the mattress.

Step 3 Pad has been placed under shoulders, neck, and head.

4. Place rolled towel under patient's neck and bath towel over patient's shoulders.
5. Brush and comb patient's hair.
6. Obtain warm water.
7. Offer patient the option of holding a face towel or washcloth over the eyes.
8. Slowly pour water from a water pitcher over hair until it is completely wet (see Step 8 illustration). If hair contains matted blood, don gloves, apply peroxide to dissolve the clots, and then rinse the hair with saline. Apply small amount of shampoo.

Step 8 Pour water over hair.

9. Work up lather with both hands. Start at the hairline and work toward back of the neck. Lift head slightly with one hand to wash back of the head. Shampoo sides of the head. Massage scalp by applying pressure with fingertips, if not contraindicated.
10. Rinse hair with water. Make sure water drains into basin. Repeat rinsing until hair is free of soap.
11. Apply conditioner or cream rinse, if requested, and rinse hair thoroughly.
12. Wrap patient's head in bath towel. Dry patient's face with cloth used to protect eyes. Dry off any moisture along the neck or shoulders.
13. Dry patient's hair and scalp. Use a second towel if first becomes saturated.
14. Comb hair to remove tangles, and dry with dryer if desired (not available in all agencies or facilities).
15. Apply oil preparation or conditioning product to hair, if desired by patient.
16. Assist patient to a comfortable position, and complete styling of hair.

preparations vary, and the application procedures, listed on the container, should be followed exactly. In some agencies, a physician's or nurse practitioner's order is necessary to shampoo the dependent patient.

Shaving. Shaving facial hair can be done after a bath or shampoo. Women may prefer to shave their legs or axillae while bathing. When assisting a patient, you should take care to avoid cutting the patient with a razor blade. Patients prone to bleeding (e.g., those receiving anticoagulants or high doses of aspirin, those with low platelet counts) must use an electric razor. Before the use of an electric razor, you should check for frayed cords and other electrical hazards, as well as your agency's policy with respect to the use of these razors. Each razor blade or electric razor should be used on only one patient because of infection-control considerations.

Before a razor blade is used for shaving, the skin must be softened to prevent pulling, scraping, or cuts. Place a warm washcloth over the male patient's face for a few seconds, then apply shaving cream or lather a mild soap to soften the skin. If the patient is unable to shave, you may perform the task. To avoid causing discomfort or razor cuts, gently pull the skin taut and use short, firm razor strokes in the direction in which the hair grows (Figure 37-9). Short downward strokes work best to remove hair over the upper lip. A patient usually can explain the best way to move the razor across the skin. In dark-skinned patients, facial hair tends to be curly and can become ingrown unless shaved close to the skin.

Moustache and Beard Care

Patients with moustaches or beards require daily grooming. Keeping these areas clean is important because food particles and mucus can easily collect in the hair. If the patient is unable to carry out self-care, you must perform this care for the patient. Beards can be gently combed out. A shaggy or unkempt moustache or beard can be trimmed, with consent from the patient or family. For cultural or religious reasons, trimming or shaving off a moustache or beard cannot be performed without the patient's or family's consent.

Figure 37-9 Shave in the direction of hair growth. Use longer strokes on the larger areas of the face. Use short strokes around the chin and lips. **Source:** Sorrentino, S. A. (2004). *Assisting with patient care* (2nd ed., p. 320, Fig 17-5). St Louis, MO: Mosby.

Care of the Eyes, Ears, and Nose

Special attention is given to cleansing the eyes, ears, and nose during a routine bath and when drainage or discharge accumulates. This aspect of hygiene not only makes patients more comfortable, it also improves sensory reception (see Chapter 47). Care focuses on preventing infection and maintaining normal sensory function and requires approaches that consider patients' special needs.

Basic Eye Care. Cleansing the eyes simply involves washing them with a clean washcloth moistened in water. Soap may cause burning and irritation (see Skill 37-1). Direct pressure should never be applied over the eyeball because it may cause serious injury. When cleansing a patient's eyes, use a clean washcloth and cleanse from the inner to outer canthus. Use a different section of the washcloth for each eye. Unconscious patients often require more frequent eye care.

Secretions may collect along the lid margins and inner canthus when the blink reflex is absent or an eye does not close completely. It may be necessary to place an eye patch over the involved eye to prevent corneal drying and irritation. Lubricating eye drops may be given according to the physician's or nurse practitioner's orders.

Eyeglasses. Glasses are made of hardened glass or plastic that is impact-resistant to prevent shattering. Nevertheless, because of their cost, extra care should be taken when cleaning glasses and they should be protected from breakage or other damage when they are not worn. Glasses should be put in a case in a drawer of the bedside table when not in use and labelled with the patient's name.

Cool water is sufficient for cleaning glass lenses. A soft cloth is best for drying to prevent scratching the lens; paper towels can scratch a lens. Plastic lenses in particular are scratched easily, and special cleansing solutions and drying cloths are available for them. Use whatever the patient's eye care specialist recommends.

Contact Lenses. A contact lens is a small, round, transparent, and sometimes coloured disc that fits directly over the cornea of the eye. Contact lenses are designed specifically to correct refractive errors of the eye or abnormalities in the cornea's shape. They are relatively easy to apply and remove.

Contact lenses are available in daily-wear, extended-wear, and disposable varieties. All lenses must be removed periodically to prevent ocular infection and corneal ulcers or abrasions. Patient education must include a discussion of proper lens care techniques in order to avoid microbial infections (e.g., keratitis) (Wu et al., 2010) (Box 37-14).

Daily-wear lenses should be removed overnight for cleaning and disinfecting; extended-wear lenses can be worn for up to 30 days without being removed (Health Canada, 2006). Disposable lenses are available in daily-wear and extended-wear varieties. Extended-wear disposable lenses are usually replaced every one to two weeks. Pain, tearing, discomfort, and redness of the conjunctivae may be symptoms of lens overwear. The persistence of symptoms after lens removal may indicate serious ocular injury.

Contact lenses accumulate secretions and foreign matter while they are being worn. These materials deteriorate and then irritate the eye, causing distorted vision and the risk for infection. Contact lenses should be cleaned and thoroughly disinfected once removed. Patients should be cautioned to never use saliva, homemade saline, or tap water when cleaning lenses as these solutions may contain microorganisms that can cause serious infections.

* BOX 37-14 PATIENT TEACHING

Contact Lens Care

Objectives

- Patient will be able to identify warning signs of corneal irritation and eye infection.
- Patient will be able to clean and care for contact lenses correctly.

Teaching Strategies

Encourage the patient to see a vision care specialist (ophthalmologist or optometrist) regularly:

- For low-risk patients: birth to 24 months, by age 3 months; age 2–5 years, prior to attending school; age 6–19 years, annually; age 20–64 years, every 1–2 years; and over age 65 years, annually; the vision care specialist will determine the frequency for high-risk patients (Alberta Association of Optometrists, n.d.)
- Teach the patient the following facts about contact lens care:
 - Special cleaning solutions should be used when cleaning and disinfecting contact lenses.
 - Never use fingernail on a lens to remove dirt or debris that does not loosen during washing with cleaning solutions.
 - Follow the recommendations of lens manufacturer or your eye care practitioner when cleaning and disinfecting lenses.
 - Remember the mnemonic RSVP: redness, sensitivity, vision problems, and pain (Health Canada, 2006). If one of these problems occurs, remove the contact lenses immediately. If problems continue, contact a vision care specialist.
 - Lenses become very slippery once cleaning solution is applied.
 - If a lens is dropped on a hard surface, moisten your finger with the cleaning or wetting solution and gently touch the lens to pick it up. Then clean, rinse, and disinfect the lens.
 - Lenses should be kept moist or wet when not worn.
 - Use fresh solution daily when storing and disinfecting lenses.
 - Do not wipe the lens with a tissue or towel.
 - Thoroughly wash and rinse the lens storage case on a daily basis. Clean it periodically with soap or liquid detergent; rinse it thoroughly with warm water and air-dry it.
 - To avoid a mix-up, always start with the same lens when removing or inserting lenses.
 - Throw away disposable or planned replacement lenses after the prescribed wearing period.

Evaluation

- Ask the patient to identify the warning signs of corneal irritation and eye infection.
- Ask the patient to describe methods of improper contact lens handling that can lead to infection.
- Ask the patient to describe the techniques required to clean and store contact lenses.

Artificial Eyes. Patients with artificial eyes have had an **enucleation**, or removal, of an entire eyeball as a result of a tumour growth, severe infection, or eye trauma. Some artificial eyes are permanently implanted, whereas others can be removed for routine cleaning. Patients with an artificial eye usually prefer to care for their own eye. You should respect the patient's wishes and assist by assembling needed equipment.

Patients may at times require assistance in prosthesis removal and cleansing. To remove an artificial eye, you retract the lower eyelid and exert slight pressure just below the eye (Figure 37-10). This action causes the artificial eye to rise from

Figure 37-10 Removal of a prosthetic eye.

the socket because the suction holding the eye in place has been broken. You may also use a small rubber bulb syringe or medicine dropper bulb to create a suction effect. The suction created by placing the bulb tip directly over the eye and squeezing lifts the artificial eye from the socket.

The artificial eye is usually made of glass or plastic. You use warm normal saline to cleanse the prosthesis. You should also cleanse the edges of the eye socket and surrounding tissues with soft gauze moistened in saline or clean tap water. Signs of infection should be reported immediately because bacteria can spread to the neighbouring eye, underlying sinuses, or even underlying brain tissue. To reinsert the eye, retract the upper and lower lids and gently slip the eye into the socket, fitting it neatly under the upper eyelid. An artificial eye may be stored in a labelled container filled with tap water or saline.

Ear Care. Routine ear care involves cleansing the ear with the end of a moistened washcloth, rotated gently into the ear canal. When cerumen is visible, a gentle, downward retraction at the entrance of the ear canal may cause the cerumen to loosen and slip out. You should warn patients never to use sharp objects such as bobby pins or paper clips to remove cerumen as this can traumatize the ear canal and rupture the tympanic membrane. Use of cotton-tipped applicators should also be avoided because they can cause cerumen to become impacted within the canal.

Children and older adults commonly have impacted cerumen. Excessive or impacted cerumen can usually be removed only by irrigation, which usually requires a physician's or nurse practitioner's order. If a patient has a history of a perforated eardrum or if perforation is discovered during assessment, the procedure is contraindicated. Before irrigation,

instill three drops of glycerine at bedtime to soften the cerumen and three drops of hydrogen peroxide twice a day to loosen the cerumen. Then irrigation with approximately 250 mL of warm water (at 37°C) into the ear canal mechanically washes away loosened cerumen. The use of cold or hot water can cause nausea or vomiting.

The patient may sit or lie on his or her side with the affected ear up. Place a small curved basin under the affected ear to catch the irrigating solution. You can use a bulb-irrigating syringe. The tip of the syringe should not occlude the ear canal to avoid exerting pressure against the tympanic membrane. Direct a gentle irrigation at the top of the canal to loosen the cerumen from the sides of the canal. After the canal is clear, wipe off any moisture from the ear and inspect the canal for remaining cerumen.

Hearing Aid Care. Hearing aids are instruments made up of miniature parts working together as a system to amplify sound in a controlled manner. Aids receive normal low-intensity sound inputs and deliver them to the ear as louder outputs. The new class of hearing aids can reduce background noise interference. Computer chips placed in the aids allow for fine adjustments to a specific patient's hearing needs. Hearing aids are used by both hard-of-hearing individuals (those with a slight or moderate hearing loss) and deaf individuals (those with severe or profound hearing loss). While mechanical dysfunction of the external or middle ear causes conductive hearing loss, which could be due to impacted cerumen or a foreign body that obstructs the transmission of sound, sensorineural (perceptive) hearing loss indicates a pathology in the inner ear, cranial nerve VII damage, or presbycusis (gradual nerve degeneration that occurs with aging) (MacDonald-Jenkins, 2009a). Although cochlear implants in children with significant hearing loss are becoming more widely available, there is no statistical information available regarding the number of children in Canada who have received cochlear implants (Fitzpatrick & Brewster, 2008). In 2010, Fitzpatrick and Brewster (2010) also undertook a survey that examined the growing use of cochlear implantation for adults. According to their results, by 2007, 2534 adults had received cochlear implants in Canada. Resource allocation and access were two of the major concerns identified in their survey with respect to the number of adult cochlear implantation surgeries.

Three popular types of hearing aids are available. An *in-the-canal (ITC) aid* is the newest, smallest, and least visible hearing aid and fits entirely in the ear canal. It has cosmetic appeal, is easy to manipulate and place in the ear, does not interfere with wearing eyeglasses or using the telephone, and can be worn during most physical exercise. However, it requires an adequate ear diameter and depth for proper fit. It does not accommodate progressive hearing loss, and it requires manual dexterity to operate, insert, remove, and change the batteries. Also, cerumen tends to plug this model more than the other models.

An *in-the-ear (ITE, or intra-aural) aid* (Figure 37-11, A) fits into the external auditory canal and allows for better fine-tuning. It is more powerful and stronger than the ITC aid and therefore is useful for a wider range of hearing loss. It is easy to position and adjust and does not interfere with wearing eyeglasses. It is, however, more noticeable than the ITC aid and is not recommended for persons with moisture or skin problems in the ear canal.

A *behind-the-ear (BTE, or postaural) aid* (Figure 37-11, B) hooks around and behind the ear and is connected by a short,

Figure 37-11 Two common types of hearing aids. A, In the ear. B, Behind the ear.

clear, hollow plastic tube to an ear mould inserted into the external auditory canal. It allows for fine-tuning. It is the largest of the three aids and is useful for patients with rapidly progressive hearing loss or manual dexterity difficulties and those who find partial ear occlusion intolerable. Disadvantages are that it is more visible, may interfere with wearing eyeglasses and using a phone, and is more difficult to keep in place during physical exercise. Box 37-15 reviews patient education guidelines for the care and use of a hearing aid.

Nasal Care. The patient can usually remove secretions from the nose by gently blowing into a soft tissue. Caution the patient against harsh blowing; this can create pressure capable of injuring the eardrum, nasal mucosa, and even sensitive eye structures. Bleeding from the nares is a sign of harsh blowing.

If the patient is unable to remove nasal secretions, assist by using a wet washcloth or a cotton-tipped applicator moistened in water or saline. The applicator should never be inserted beyond the length of the cotton tip. Excessive nasal secretions can also be removed by gentle suctioning.

When patients have a nasogastric, feeding, or endotracheal tube inserted through the nose, you should change the tape anchoring when soiled or if it becomes loose. When tape becomes moist from nasal secretions, the skin and mucosa can easily become macerated. Friction from the tube can cause tissue sloughing. After carefully removing the tape, maintain your hold of the tubing and thoroughly cleanse and dry the nasal surface (see Chapter 42).

► BOX 37-15 Care and Use of Hearing Aids

- Initially wear a hearing aid for short periods; then gradually increase the wearing time to 10–12 hours.
- Once inserted, turn the aid slowly to one-third to one-half volume.
- Remember that a whistling sound indicates too high a volume, incorrect ear mould insertion, an improper fit of the aid, or a buildup of earwax or fluid.
- Adjust the volume to a comfortable level for talking at a distance of 1 m.
- Do not wear the aid under heat lamps, while using a hair dryer, or in very wet, cold weather.
- Keep in mind that batteries can last 70–85 hours—one week with daily wearing of 10–12 hours.
- Remove or disconnect the battery when not in use.
- Replace ear moulds every 2–3 years.
- Routinely check the battery compartment: Is it clean? Are batteries inserted properly? Is the compartment shut all the way?
- Remember that dials on the hearing aid should be clean and easy to rotate, creating no static during adjusting.
- Keep the aid clean.
- Aids are usually cleaned with a soft cloth and warm soapy water; see the manufacturer's instructions.
- Avoid the use of hairspray and perfume while wearing the hearing aid; the residue from the spray can cause the aid to become oily and greasy.
- Do not submerge the aid in water.
- Routinely check the cord or tubing (depending on type of aid) for cracking, fraying, and poor connections.
- Follow up with an audiologist routinely to evaluate the effectiveness of the current aid.
- Remember that the frequencies of newer computerized hearing aids can be easily adjusted.

Data from Ebersole, P., Hess, P., Touhy, T. A., Jett, K., & Luggen, A. (2008). *Toward healthy aging: Human needs and nursing response* (7th ed.). St Louis, MO: Mosby; Eliopoulos, C. (2005). *Gerontological nursing* (6th ed.). Philadelphia, PA: Lippincott Williams & Wilkins; and Miller, C. A. (2009). *Nursing for wellness in older adults* (5th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Patient's Room Environment

Attempting to make a patient's room as comfortable as possible is an important priority. The patient's room should be comfortable, safe, and large enough to allow the patient and visitors to move about freely. Room temperature and ventilation are difficult to control; however, noise and odours can be controlled to create a more comfortable environment. Keeping the room neat and orderly also contributes to the patient's sense of well-being.

Maintaining Comfort. The nature of what constitutes a comfortable environment depends on the patient's age, severity of illness, and level of daily activity. Depending on the patient's age and physical condition, the room temperature should be maintained between 20°C and 23°C, if possible. Infants, older adults, and the acutely ill may need a warmer room. However, certain acutely ill patients (e.g., patients with head injuries) benefit from cooler room temperatures to lower the body's metabolic demands.

A good ventilation system keeps stale air and odours from lingering in the room. The acutely ill, infants, and older adults

Figure 37-12 A typical hospital room.

must be protected from drafts by ensuring that they are adequately dressed and covered with a lightweight blanket.

Good ventilation also reduces lingering odours caused by draining wounds, vomitus, bowel movements, and unemptied urinals. Room deodorizers can help remove many unpleasant odours but should be used with discretion in consideration of the patient's possible embarrassment. Before using room deodorizers, it is important to determine that the patient is not allergic or sensitive to the deodorizer itself. Bedpans and urinals should be emptied and rinsed promptly. Thorough hygiene measures are the best way to control body or breath odours.

Ill patients seem to be more sensitive to common hospital noises (e.g., IV pump alarms, suction apparatus, or stretchers exiting an elevator). You should explain the source of any unfamiliar noise to the patient and family members. Until the patient is familiar with hospital noises, the noise level should be controlled as much as possible. This can also help the patient sleep (see Chapter 40).

Proper lighting is necessary for everyone's safety and comfort. A brightly lit room is usually stimulating, and a darkened room is best for rest and sleep. Room lighting can be adjusted by closing or opening drapes, regulating overbed lights, and closing or opening room doors. When entering a patient's room at night, refrain from abruptly turning on an overhead light unless necessary.

Room Equipment. Although variations in hospital rooms exist across health care settings, a typical hospital room contains the following basic pieces of furniture: an overbed table, a bedside stand, chairs, and a bed (Figure 37-12). Long-term care and rehabilitation facilities may have similar equipment. The overbed table rolls on wheels and can be adjusted to various heights over the bed or a chair. The table provides an ideal working space for performing procedures. It also provides a surface on which to place meal trays, toiletry items, and objects frequently used by the patient. The bedpan and urinal should not be placed on the overbed table. The bedside stand is used to store the patient's personal possessions and hygiene equipment. A telephone (if supplied), water pitcher, and drinking cup are commonly found on top of the bedside stand.

Figure 37-13 Instruct patient in use of call light and bed controls.

Most hospital rooms contain an armless straight-backed chair or an upholstered lounge chair with arms. Straight-backed chairs are convenient to use when temporarily transferring the patient from the bed, such as during bed making. Lounge chairs tend to be more comfortable when a patient is willing and able to sit for an extended period.

Each room usually has an overbed light. Additional portable lighting can be used to provide extra light during bedside procedures. Other equipment usually found in a patient's room is a call bell, a television set (not available in all agencies and facilities), a wall-mounted blood pressure gauge, oxygen and vacuum wall outlets, and personal-care items. Special equipment designed for comfort or positioning patients includes foot boots, special mattresses, and bed boards (see Chapters 45 and 46). Check your agency's policy and the manufacturers' directions before using comfort and positioning equipment.

Beds. Seriously ill patients may remain in bed for a long time. Because a bed is the piece of equipment used most by a hospitalized patient, it should be designed for comfort, safety, and adaptability for changing positions. The typical hospital bed has a firm mattress on a metal frame that can be raised and lowered horizontally. Many hospitals are converting the standard hospital bed to one in which the mattress surface can be electronically adjusted for patient comfort. Different bed positions are used to promote patient comfort, minimize symptoms, promote lung expansion, and improve access during certain procedures (Table 37-6).

The position of a bed is usually changed by electrical controls incorporated into the patient's call light and in a panel on the side or foot of the bed (Figure 37-13). However, some facilities do have hospital beds that are manually controlled. It is important to become familiar with the use of the bed controls. Ease in raising and lowering a bed and in changing the position of the bed head and foot eliminates undue musculoskeletal strain on the care provider. Instructions should be provided to the patients on the proper use of controls; caution them against raising the bed to a position that might cause harm.

Beds contain safety features such as locks on the wheels or casters, and alarms. Wheels should be locked when the bed is stationary to prevent accidental movement. Alarms should be turned on to protect patients at risk for falls when getting out

TABLE 37-6 Common Bed Positions

Position	Description	Uses
Fowler's	Head of bed raised to angle of 45 degrees or more; semisitting position; foot of bed may also be raised at knee	Is preferred while patient eats Is used during nasogastric tube insertion and nasotracheal suction Promotes lung expansion
Semi-Fowler's	Head of bed raised approximately 30 degrees; inclination less than Fowler's position; foot of bed may also be raised at knee	Promotes lung expansion Is used when patients receive gastric feedings to reduce regurgitation and risk of aspiration
Trendelenburg's	Entire bed frame tilted with head of bed down	Is used for postural drainage Facilitates venous return in patients with poor peripheral perfusion
Reverse Trendelenburg's	Entire bed frame tilted with foot of bed down	Is used infrequently Promotes gastric emptying Prevents esophageal reflux
Flat	Entire bed frame horizontally parallel with floor	Is used for patients with vertebral injuries and in cervical traction Is used for patients who are hypotensive Is generally preferred by patients for sleeping

of bed without assistance. Side rails protect patients from accidental falls. The headboard can be removed from most beds. This is important when the medical team must have easy access to the patient's head, such as during cardiopulmonary resuscitation.

Bed Making. A patient's bed should be kept clean and comfortable. This requires frequent inspections to be sure linen is clean, dry, and free of wrinkles. When patients are diaphoretic, have draining wounds, or are incontinent, you should check frequently for soiled linen.

The bed is usually made in the morning after the patient's bath or while the patient is in the shower, sitting in a chair

eating, or out of the room for procedures or tests. Throughout the day, bed linens should be straightened when they become loose or wrinkled. The bed linen should also be checked for food particles after meals and for wetness or soiling. Linens that are soiled or wet should be changed.

When changing bed linen, follow the principles of medical asepsis by keeping soiled linen away from your uniform (Figure 37-14). Soiled linen is placed in special linen bags before discarding it in a hamper. To avoid air currents, which can spread microorganisms, bed linens should never be shaken. To avoid transmitting infection, do not place soiled linen on the floor. If clean linen touches the floor, it should be immediately discarded.

During bed making, use proper body mechanics (see Chapter 35). You should always raise the bed to the appropriate height before changing linen so that you do not have to bend or stretch over the mattress. You should also move back and forth to opposite sides of the bed while putting on new linen. Body mechanics is also important when turning or repositioning the patient in bed.

When patients are confined to a bed, organize bed-making activities to conserve time and energy (Skill 37-5). The patient's privacy, comfort, and safety are all important. To help promote comfort and safety, use side rails to aid positioning and turning,

keep a call light within the patient's reach, and maintain the proper bed position. After making a bed, always return it to the lowest horizontal position to prevent accidental falls should the patient get in and out of the bed alone.

Text continued on p. 873

Figure 37-14 Holding linen away from the uniform prevents contact with microorganisms.

► SKILL 37-5 Making an Occupied Bed

Delegation Considerations

The skill of making an occupied bed can be delegated to an unregulated care provider (UCP). It is important to discuss the following with the UCP:

- Any precautions or activity restrictions for the patient
- What to do if wound drainage, dressing material, drainage tubes, or IV tubing becomes dislodged or is found in the linens
- What to do if the patient becomes fatigued

Equipment

See Figure 37-15.

- Linen bag(s)
- Bottom sheet (flat or fitted)
- Drawsheet (optional)
- Top sheet
- Blanket
- Bedspread
- Waterproof pads or soaker pad (optional)
- Pillowcases
- Bedside chair or table
- Disposable gloves (optional)
- Towel
- Disinfectant

Procedure

STEPS

1. Assess potential for patient incontinence or excess drainage on bed linen.
2. Check chart for orders or specific precautions concerning movement and positioning.
3. Explain procedure to the patient, noting that he or she will be asked to turn on side and roll over linen.
4. Perform hand hygiene and put on gloves. (Gloves are worn only if linen is soiled or if contact with body secretions is possible.)
5. Assemble equipment and arrange it on a bedside chair or table. Remove unnecessary equipment such as a dietary tray or items used for hygiene.
6. Draw room curtain around bed or close room door.
7. Adjust bed height to a comfortable working position. Lower any raised side rail on one side of bed. Remove the call light.
8. Loosen top linen at foot of the bed.

RATIONALE

- Determines the need for protective waterproof pads or extra bath blankets on the bed.
- Ensures patient safety and the use of proper body mechanics.
- Minimizes anxiety and promotes cooperation.
- Reduces the transmission of microorganisms.
- Assembling all equipment provides for a smooth procedure and assists in increasing patient's comfort. Placing linen on clean surface minimizes spread of infection.
- Maintains patient's privacy.
- Minimizes strain on the back. It is easier to remove and put on linen evenly with bed in a flat position. Provides easy access to bed and linen.
- Makes linen easier to remove.

SKILL 37-5 Making an Occupied Bed—cont'd

9. Remove bedspread and blanket separately. If bedspread and blanket are soiled, place them in a linen bag. Keep soiled linen away from your uniform.
 10. If blanket and bedspread are to be reused, fold them by bringing the top and bottom edges together. Fold the farthest side over onto nearer bottom edge. Bring top and bottom edges together again. Place folded linen over back of chair.
 11. Cover patient with a bath blanket in the following manner: Unfold bath blanket over top sheet. Ask patient to hold top edge of the bath blanket. If patient is unable to help, tuck top of bath blanket under patient's shoulder. Grasp top sheet under bath blanket at patient's shoulders and bring sheet down to foot of bed. Remove the sheet and discard in a linen bag.
 12. With assistance from another, slide mattress toward head of the bed.
 13. Position the patient on the far side of the bed, turned onto his or her side and facing away from you. Be sure side rail in front of patient is up. Adjust pillow under patient's head.
 14. Loosen bottom linens, moving from head to foot. With seam side down (facing the mattress), fanfold bottom sheet and drawsheet toward patient—first drawsheet, then bottom sheet. Tuck edges of linen just under buttocks, back, and shoulders. Do not fanfold mattress pad if it is to be reused (see Step 14 illustration).
 15. Wipe off any moisture on exposed mattress with towel and appropriate disinfectant.
 16. Put on clean linen to exposed half of the bed:
 - A. Place clean mattress pad on bed by folding it lengthwise with centre crease in middle of bed. Fanfold top layer over mattress. (If pad is reused, simply smooth out any wrinkles.)
 - B. Unfold bottom sheet lengthwise so that centre crease is situated lengthwise along centre of bed. Fanfold sheet's top layer toward centre of bed alongside the patient. Smooth bottom layer of sheet over mattress, and bring the edge over closest side of the mattress. Pull fitted sheet smoothly over mattress ends. Allow edge of flat unfitted sheet to hang about 25 cm over mattress edge. Lower hem of bottom flat sheet should lie seam down and even with bottom edge of mattress (see Step 16B illustration).
- Reduces the transmission of microorganisms.
 - Folding method facilitates replacement and minimizes wrinkles.
 - Bath blanket provides warmth and keeps body parts covered during linen removal.
 - If mattress slides toward foot of the bed when head of the bed is raised, it is difficult to tuck in linen. In addition, it is uncomfortable for the patient because the patient's feet may be pressed against or hang over the foot of the bed.
 - Turning patient onto side provides space for placement of clean linen. Side rail ensures patient's safety from forward falls from the bed surface and helps patient in moving.
 - Prepares for removal of all bottom linen simultaneously. Provides maximum workspace for placing clean linen. Later, when patient turns to other side, soiled linen can be removed easily.
 - Reduces the transmission of microorganisms.
 - Putting on linen over bed in successive layers minimizes energy and time used in bed making.
 - Proper positioning of linen on one side ensures that adequate linen will be available to cover opposite side of bed. Keeping seam edges down eliminates irritation to patient's skin.

Step 14 Old linen tucked under patient.

Step 16B Clean linen applied to bed.

Continued

► SKILL 37-5 Making an Occupied Bed—cont'd

17. Mitre bottom flat sheet at head of bed:

- A. Face head of bed diagonally. Place hand away from head of bed under top corner of mattress, near mattress edge, and lift.
- B. With other hand, tuck top edge of bottom sheet smoothly under mattress so that side edges of sheet above and below the mattress would meet if brought together.
- C. Face side of the bed and pick up top edge of sheet at approximately 45 cm from top of mattress (see Step 17C illustration).
- D. Lift sheet, and lay it on top of mattress to form a neat triangular fold, with lower base of the triangle even with the mattress side edge (see Step 17D illustration).

Step 17C Pick up top edge of sheet.

- E. Tuck lower edge of sheet, which is hanging free below the mattress, under the mattress. Tuck with palms down, without pulling triangular fold (see Step 17E illustration).
- F. Hold portion of sheet covering side of mattress in place with one hand. With the other hand, pick up top of triangular linen fold and bring it down over side of the mattress (see Step 17F illustrations). Tuck this portion under mattress (see Step 17F illustrations).

Step 17E Lower edge of sheet tucked under mattress.

Step 17D Sheet on top of mattress in a triangular fold.

Step 17F A and B, Triangular fold placed over side of mattress. C, Linen tucked under mattress.

18. Tuck remaining portion of sheet under the mattress, moving toward foot of the bed. Keep linen smooth.
19. (Optional) Open drawsheet so that it unfolds in half. Lay centrefold along middle of bed lengthwise, and position sheet so that it will be under the patient's buttocks and torso (see Step 19 illustration). Fanfold top layer toward patient, with edge along the patient's back. Smooth bottom layer out over the mattress, and tuck excess edge under mattress (keep palms down).
20. Place waterproof pad over drawsheet, with centrefold against patient's side. Fanfold top layer toward patient.
21. Have patient roll slowly toward you, over the layers of linen. Raise side rail on working side, and go to other side of the bed.

- Mitred corner cannot be loosened easily even if patient moves frequently in bed.

- Folds of linen are source of irritation.
- Drawsheet is used to lift and reposition the patient. Placement under patient's torso distributes most of the patient's body weight over the sheet.
- Protects bed linen from being soiled.
- Positions patient for removal and placement of linens. Maintains patient's safety and body alignment during turning.

► SKILL 37-5 Making an Occupied Bed—cont'd

22. Lower side rail. Assist patient in positioning on other side, over folds of linen (see Step 22 illustration). Loosen edges of soiled linen from under mattress.

Step 19 Optional drawsheet.

23. Remove soiled linen by folding it into a bundle or square, with soiled side turned in. Discard in linen bag. If necessary, wipe mattress with antiseptic solution, and dry mattress surface before putting on new linen.
24. Pull clean, fanfolded linen smoothly over edge of mattress from head to foot of bed.
25. Assist patient in rolling back into supine position. Reposition pillow.
26. Pull fitted sheet smoothly over mattress ends. Mitre top corner of bottom sheet (see Step 17). When tucking corner, be sure that sheet is smooth and free of wrinkles.
27. Facing side of the bed, grasp remaining edge of bottom flat sheet. Lean back; keeping back straight, pull while tucking excess linen under mattress. Proceed from head to foot of the bed. (Avoid lifting mattress during tucking to ensure fit.)
28. Smooth fanfolded drawsheet out over bottom sheet. Grasp edge of the sheet with palms down, lean back, and tuck sheet under mattress. Tuck from middle to top and then to bottom.
29. Place top sheet over patient with centrefold lengthwise down middle of bed. Open sheet from head to foot, and unfold over patient.
30. Ask patient to hold clean top sheet, or tuck sheet around patient's shoulders. Remove the bath blanket and discard in linen bag.
31. Place blanket on bed, unfolding it so that crease runs lengthwise along middle of bed. Unfold blanket to cover patient. Top edge should be parallel with edge of top sheet and 15–20 cm from top sheet's edge.
32. Place bedspread over bed according to Step 31. Be sure that top edge of bedspread extends about 2.5 cm above blanket's edge. Tuck top edge of bedspread over and under top edge of blanket.
33. Make cuff by turning edge of top sheet down over top edge of the blanket and bedspread.

- Exposes opposite side of bed for removal of soiled linen and placement of clean linen. Makes linen easier to remove.

Step 22 Assist patient to roll over folds of linen.

- Reduces the transmission of microorganisms.
- Smooth linen will not irritate patient's skin.
- Maintains patient's comfort.
- Wrinkles and folds can cause irritation to the skin.
- Proper use of body mechanics while tucking linen prevents injury.
- Tucking first at top or bottom may pull sheet sideways, causing poor fit.
- Sheet should be equally distributed over bed by correctly positioning centrefold.
- Sheet prevents exposure of body parts. Having patient hold sheet encourages patient participation in care.
- Blanket should be placed to cover patient completely and provide adequate warmth.
- Gives bed neat appearance and provides extra warmth.
- Protect patient's face from rubbing against blanket or bedspread.

Continued

► SKILL 37-5 Making an Occupied Bed—cont'd

34. Standing on one side at foot of the bed, lift mattress corner slightly with one hand and tuck linens under mattress. Tuck top sheet and blanket under together. Be sure that linens are loose enough to allow movement of patient's feet. Making a horizontal toe pleat is an option (see Step 34 illustration).

Step 34 Optional toe pleat.

35. Make modified mitred corner with top sheet, blanket, and bedspread (see Box 37-16, Step 20 illustration):
- Pick up side edge of top sheet, blanket, and bedspread approximately 45 cm from foot of the mattress. Lift linen to form triangular fold, and lay it on bed.
 - Tuck lower edge of sheet, which is hanging free below mattress, under the mattress. Do not pull triangular fold.
 - Pick up triangular fold, and bring it down over mattress while holding linen in place along side of the mattress. Do not tuck tip of triangle.
36. Raise side rail. Make other side of bed; spread sheet, blanket, and bedspread out evenly. Fold top edge of bedspread over the blanket and make cuff with top sheet (see Step 33); make modified mitred corner at foot of bed (see Step 35).
37. Change pillowcase:
- Have patient raise his or her head. While supporting patient's neck with one hand, remove pillow. Allow patient to lower head.
 - Remove soiled case by grasping pillow at open end with one hand and pulling case back over pillow with the other hand. Discard case in linen bag.
 - Grasp clean pillowcase at centre of closed end. Gather case, turning it inside out over the hand holding it. With the same hand, pick up the middle of one end of the pillow. Pull pillowcase down over pillow with the other hand.
 - Be sure pillow corners fit evenly into corners of the pillowcase. Place pillow under the patient's head.
38. Place call bell within the patient's reach, and return the bed to comfortable position.
39. Open room curtains, and rearrange furniture. Place personal items within easy reach on overbed table or bedside stand. Return bed to a comfortable height.
40. Discard dirty linen in a hamper or chute, remove your gloves, and perform hand hygiene.
41. Ask whether patient feels comfortable.
42. While you are performing this skill, inspect the skin for areas of irritation.
43. Observe the patient for signs of fatigue, dyspnea, pain, or discomfort throughout the skill.
- Makes neat-appearing bed. Pressure ulcers can develop on patient's toes and heels from feet rubbing against tight-fitting bed sheets.
 - Ensures top covers will not loosen easily.
 - Secures top linen but keeps even edge of blanket and top sheet draped over mattress.
 - Side rail protects patient from accidental falls.
 - Support of neck muscles prevents injury during flexion and extension of neck.
 - Pillows slide out easily, thus minimizing contact with soiled linen.
 - Eases sliding of pillowcase over pillow.
 - Poorly fitting case constricts fluffing and expansion of the pillow and interferes with patient comfort.
 - Ensures patient safety and comfort.
 - Promotes sense of well-being.
 - Prevents the transmission of microorganisms.
 - Ensures bed linens are clean and smooth.
 - Folds in linen can cause pressure on the skin.
 - Provides data about patient's level of activity tolerance and ability to participate in other procedures.

► SKILL 37-5 Making an Occupied Bed—cont'd

Unexpected Outcomes

Discomfort caused by linen fold

Signs of breakdown of patient's skin

Recording and Reporting

- Making an occupied bed need not be recorded.

Related Interventions

- Tighten sheets.
- Change patient's position frequently.
- Institute skin care measures to reduce risk of pressure ulcer (see Chapter 46).
- Change patient's position frequently.

Figure 37-15 Equipment for making an occupied bed.

Figure 37-16 Surgical or recovery bed.

When possible, a bed should be made while it is unoccupied (Box 37-16). Clinical judgement is used regarding the best time to have the patient sit up in a chair while the bed is made. When making an unoccupied bed, follow the basic principles for making an occupied bed.

An unoccupied bed can be open or closed. In an open bed, the top covers are folded back so that a patient can easily get into bed. In a closed bed, the top sheet, blanket, and bedspread are drawn up to the head of the mattress and under the pillows. A closed bed is prepared in a hospital room before a new patient is admitted to that room.

A surgical, recovery, or postoperative bed is a modified version of the open bed. The top bed linen is arranged for easy transfer of the patient from a stretcher to the bed. The top sheets and bedspread are not tucked or mitred at the corners. Instead, the top sheets are folded to one side or to the bottom third of the bed (Figure 37-16). This makes it easier to transfer the patient into the bed.

Linens. In any health care agency, it is important to have an adequate supply of linen to care appropriately for patients. Many agencies have “nurse servers,” either within or just outside a patient’s room, where a daily supply of linen is stored. Because of the emphasis on cost control in health care, it is important to not bring excess linen into a patient’s room. Linen brought into a patient’s room, if unused, must be discarded for laundering, which can increase an agency’s costs. Excess linen lying around a patient’s room creates clutter and obstacles for patient care activities.

Before bed making, it is important to collect necessary bed linen and the patient’s personal items. In this way, you have all equipment accessible to prepare the bed and room. Linens are pressed and folded to prevent the spread of microorganisms and to make bed making easier. When fitted sheets are not available, flat sheets usually are pressed with a centre crease to be placed down the centre of the bed. The linen unfolds easily to the sides, with creases often fitting over the mattress edge. A complete linen change is not always necessary. The sheet, blanket, and bedspread may be reused for the same patient if they are not wet or soiled.

Disposal of linen must be done to minimize the spread of infection (see Chapter 32). Agency policies provide guidelines for the proper way to bag and dispose of soiled linen. After a patient is discharged, all bed linen is sent to the laundry, the mattress and bed are cleaned by housekeeping staff, and new bed linen is applied.

❖ Evaluation

Patient Care

Evaluation of hygiene measures occurs both during and after each particular skill. For example, while bathing a patient, closely inspect the skin to determine whether drainage or other soiling has been effectively removed from the skin’s surface. Once the bath is completed, ask the patient whether his or her comfort and relaxation have improved. When evaluating for the effectiveness of hygiene measures, observe for changes in

► BOX 37-16 Procedural Guideline

Making an Unoccupied Bed

Delegation Considerations:

The skill of making an unoccupied bed can be delegated to an unregulated care provider (UCP).

Equipment:

- Linen bag
- Bottom sheet (flat or fitted)
- Drawsheet (optional)
- Top sheet
- Blanket
- Bedspread
- Waterproof pads or soaker pad (optional)
- Pillowcases
- Bedside chair or table
- Disposable gloves (if linen is soiled)
- Washcloth
- Antiseptic cleanser

Procedure:

1. Determine whether patient has been incontinent or excess drainage is on linen. Gloves will be necessary.
2. Assess activity orders or restrictions in mobility to plan whether patient can get out of bed for the procedure. If so, assist patient to bedside chair or recliner.
3. Raise bed to a comfortable working position. Lower the side rails on both sides of the bed.
4. Remove soiled linen and place in linen bag. Avoid shaking or fanning linen.
5. Reposition mattress and wipe off any moisture using a washcloth moistened in antiseptic solution. Dry thoroughly.
6. Put on all bottom linen on one side of bed before moving to opposite side.
7. Be sure fitted sheet is placed smoothly over mattress. To put on a flat unfitted sheet, allow about 25 cm to hang over mattress edge. Lower hem of the sheet should lie seam down, even with bottom edge of the mattress. Pull remaining top portion of sheet over top edge of the mattress.
8. While standing at head of the bed, mitre top corner of bottom sheet (see Skill 37-5, Step 17).
9. Tuck remaining portion of unfitted sheet under the mattress.
10. *Optional and agency or facility specific:* Put on a drawsheet, laying centre fold along middle of the bed lengthwise. Smooth drawsheet over the mattress and tuck excess edge under mattress, keeping palms down.
11. Move to opposite side of the bed, and spread bottom sheet smoothly over edge of mattress from head to foot of the bed.
12. Put on fitted sheet smoothly over each mattress corner. For an unfitted sheet, mitre the top corner of bottom sheet (see Skill 37-5, Step 17), making sure corner is taut.
13. Grasp remaining edge of unfitted bottom sheet and tuck tightly under the mattress while moving from head to foot of the bed. Smooth folded drawsheet over the bottom sheet and tuck under mattress, first at middle, then at top, and then at bottom.
14. If needed, put on a waterproof pad or soaker pad over bottom sheet.
15. Place top sheet over bed with vertical centre fold lengthwise down middle of the bed. Open sheet out from head to foot, being sure top edge of the sheet is even with top edge of the mattress.
16. Make horizontal toe pleat: Stand at foot of bed and fanfold in sheet 5–10 cm across bed. Pull sheet up from bottom to make fold approximately 15 cm from bottom edge of the mattress (see Skill 37-5, Step 34).
17. Tuck in remaining portion of the sheet under foot of mattress. Place blanket over the bed with top edge parallel to top edge of sheet and 15–20 cm down from edge of sheet. (*Optional:* Put on additional bedspread over bed.)
18. Make cuff by turning edge of top sheet down over top edge of the blanket and bedspread.
19. Standing on one side at foot of the bed, lift mattress corner slightly with one hand, and with the other hand tuck top sheet, blanket, and bedspread under the mattress. Be sure toe pleats are not pulled out.
20. Make modified mitred corner with top sheet, blanket, and bedspread. After triangular fold is made, do not tuck tip of triangle (see Step 20 illustration).
21. Go to other side of the bed. Spread sheet, blanket, and bedspread out evenly. Make cuff with top sheet and blanket. Make modified corner at foot of the bed.
22. Put on clean pillowcase.
23. Place call light within patient's reach on a bed rail or pillow and return bed to height allowing for patient transfer. Assist the patient to get into bed.
24. Arrange patient's room. Remove and discard supplies. Perform hand hygiene.

Step 20 Modified mitred corner.

the patient's behaviour. Does the patient assume a more relaxed position? Is the patient free of body odour? Is the patient able to fall asleep? Does the patient's facial expression convey a sense of comfort?

Frequently, it takes time for hygiene care to result in an improvement in a patient's condition. The presence of oral lesions, a scalp infestation, or skin excoriation often requires repeated measures and a combination of nursing interventions. Evaluate for improvement in the patient's

condition over time and determine whether existing therapies are effective.

Throughout evaluation, consider the goals of care and evaluate whether expected outcomes are achieved. A critical thinking approach ensures that consideration is given to all factors when evaluating a patient's care (Figure 37-17). Knowledge base and experience provide important perspectives when analyzing observations made about a patient. For example, once you have seen how dehydration of the oral mucosa clears

Figure 37-17 Critical thinking model for hygiene evaluation.

with repeated hygiene, it helps you to recognize when progress in another patient is slow. The standards for evaluation are the expected outcomes established in the planning stage of the patient's care. If outcomes are not met, the care plan may need to be revised. Continual application of critical thinking and clinical judgement is necessary when considering all evaluation findings.

Patient Expectations

The final portion of the evaluation considers whether a patient's expectations have been met through hygiene care. You might ask the patient, "Do you feel your bath and back rub helped to make you comfortable?" "Can you suggest ways in which we can improve your foot care?" "What further measures do you think are necessary to keep your mouth clean and refreshed?"

Patients' expectations are important guidelines in determining patient satisfaction. As the care provider, you must feel comfortable in addressing your patients' concerns and expectations. A caring approach can facilitate a discussion of these issues.

✦ KEY CONCEPTS

- Determine a patient's ability to perform self-care and provide hygiene care according to the patient's needs and preferences.
- During hygiene, integrate other activities such as physical assessment, wound care, and ROM exercises.

- While providing daily hygiene needs, use teaching and communication skills in developing a caring relationship with the patient.
- Various personal, sociocultural, socioeconomic, and developmental factors influence patients' hygiene practices.
- Patients' health beliefs predict the likelihood of their assuming health-promoting behaviour, such as the maintenance of good hygiene.
- You might not assess all body regions before administering hygiene; however, routine assessment of the patient's condition is undertaken whenever care is given.
- Patients with reduced sensation, vascular insufficiency, and immobility are at greater risk for impaired skin integrity.
- You must perform an assessment of each patient's physical and cognitive abilities to perform basic hygiene measures, including muscle strength, flexibility and dexterity, balance, coordination, activity tolerance, and ability to comprehend. For patients suffering symptoms such as pain or nausea, administering symptom relief therapies before performing hygiene procedures better prepares the patient.
- Patients with diabetes mellitus require special nail and foot care.
- When administering oral care to unconscious patients, measures must be taken to prevent aspiration.
- A patient's room should be comfortable, safe, and uncluttered to provide for patient comfort and safety.
- An evaluation of hygiene care is based on the patient's sense of comfort, relaxation, well-being, and understanding of hygiene techniques.

✦ CRITICAL THINKING EXERCISES

1. Jack Hines, a 19-year-old, remains in hospital after a motorcycle accident in which he suffered multiple traumatic injuries. Jack has limited mobility due to casts to his left leg and arm. Discuss important factors to consider when administering hygiene care. Identify two nursing diagnoses and interventions with rationales.
2. Marian Goyeau, a 40-year-old woman, was admitted into hospital for treatment of a malignant breast lesion. Marian is undergoing chemotherapy along with radiation treatment. During your assessment, she complains of a loss of appetite, nausea and vomiting, and sores in her mouth. Marian is suffering from stomatitis. Identify two nursing diagnoses and interventions with rationales.
3. Michelle Tweed, a 78-year-old woman, was transferred from an acute care hospital to a rehabilitation facility after a cerebrovascular accident. She exhibits right hemiparesis and aphasia and is incontinent of urine and stool. During the initial assessment, you discover that Mrs. Tweed has reddened areas on both heels, and her perineum and buttocks are excoriated. Identify two priority nursing diagnoses. Discuss at least three factors that contributed to Mrs. Tweed's impaired skin integrity.

✦ REVIEW QUESTIONS

1. Mr. Mazzuca presents with an ulcer on his left foot. His diabetes mellitus is considered when planning care for him. In providing teaching on foot care, which of the following is most important to include?
 1. Daily inspection of his feet
 2. Application of lotion to his feet and between his toes daily
 3. Daily soaking of his feet in hot water
 4. Cutting his toenails in the shape of a curve

2. A 35-year-old man is interested in obtaining information about the cause of his psoriasis. Which of the following should be included in the patient teaching?
 1. Psoriasis is contagious.
 2. Psoriasis can be related to poor hygiene.
 3. Psoriasis is not contagious.
 4. Psoriasis can be cured.
3. A 75-year-old woman who has a history of diabetes and peripheral vascular disease has been trying to remove a corn from the bottom of her foot with a pair of scissors. Patient teaching should include which of the following?
 1. Increased circulation in her feet could cause severe bleeding if she were to injure her foot with the scissors.
 2. Peripheral vascular disease increases her risk of developing more corns.
 3. Diabetes mellitus places her at an increased risk for infection if she has an open wound on her foot.
 4. Her chronic disease limits her range of motion, and she may not be able to safely see or reach the corn on the bottom of her foot.
4. A thorough skin assessment is very important because the skin can provide information about which of the following?
 1. Support systems
 2. Circulatory status
 3. Psychological wellness
 4. Fundamental skills
5. A dark-skinned patient is in the intensive care unit after a motor vehicle collision. In assessing for cyanosis, you would expect to find which characteristics in this patient's skin?
 1. Ruddy colour
 2. Generalized pallor
 3. Ashen, grey, or dull appearance
 4. Patchy areas of pallor
6. When assessing for inflammation in a darkly pigmented patient, you would do which of the following?
 1. Assess the skin for swelling
 2. Palpate the skin for edema and increased warmth
 3. Assess the oral mucosa for cyanosis
 4. Palpate the skin for tenderness
7. Before providing mouth care to an unconscious patient, which of the following should be considered first?
 1. Presence of a gag reflex
 2. Condition of the skin
 3. Presence of pain
 4. Availability of equipment
8. When providing hair care for a patient, which of the following is not an important consideration?
 1. Caregiver preferences
 2. Family preferences
 3. Cultural preferences
 4. Patient preferences
9. Which of the following is the correct technique when providing eye care?
 1. Eyes should be cleansed from the outer to the inner canthus.
 2. Eyes should be cleansed from the inner to the outer canthus.
 3. Eye hygiene is not necessary.
 4. It is acceptable to cleanse eyes from either direction.
10. Which of the following is important to consider when providing hygiene care for patients?
 1. Use communication skills that promote a caring therapeutic relationship.
 2. Provide privacy, convey respect, and promote independence.
 3. Provide an environment that promotes the patient's physical and mental comfort.
 4. All of the above.

Rationales for the Review Questions appear at the end of the book.

Cardiopulmonary Functioning and Oxygenation

Original chapter by Paulette M. Archer, RN, EdD

Canadian content written by Giuliana Harvey, RN, MN

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Describe the structure and function of the cardiopulmonary system.
- Identify the physiological processes of cardiac output, myocardial blood flow, and coronary artery circulation.
- Diagram the electrical conduction system of the heart.
- Describe the relationship among cardiac output, preload, afterload, contractility, and heart rate.
- Identify the physiological processes involved in ventilation, perfusion, and exchange of respiratory gases.
- Describe the neural and chemical regulation of respiration.
- Describe the impact of a patient's level of health and age, lifestyle, and environment on tissue oxygenation.
- Identify and describe clinical outcomes as a result of disturbances in conduction, altered cardiac output, impaired valvular function, myocardial ischemia, and impaired tissue perfusion.
- Identify and describe clinical outcomes of hyperventilation, hypoventilation, and hypoxemia.
- Identify nursing care interventions in the primary care, acute care, and restorative and continuing care settings that promote oxygenation.

Oxygen is required to sustain life. The cardiac and respiratory systems function to supply the body's oxygen demands. Blood is oxygenated through the mechanisms of ventilation, perfusion, and transport of respiratory gases. Neural and chemical regulators

control the rate and depth of respiration in response to tissue's changing oxygen demands.

Scientific Knowledge Base

Cardiovascular Physiology

Cardiopulmonary physiology involves delivery of (a) deoxygenated blood (blood high in carbon dioxide and low in oxygen) to the right side of the heart and to the pulmonary circulation and (b) oxygenated blood from the lungs to the left side of the heart and the tissues. The cardiac system delivers oxygen, nutrients, and other substances to the tissues and removes the waste products of cellular metabolism through the cardiac pump, the circulatory vascular system, and the integration of other systems (e.g., respiratory, digestive, and renal) (McCance & Huether, 2005).

Structure and Function. The right ventricle pumps blood through the pulmonary circulation. The left ventricle pumps blood to the systemic circulation (Figure 38-1). The circulatory system exchanges respiratory gases, nutrients, and waste products between the blood and the tissues.

Myocardial Pump. The pumping action of the heart is essential to maintaining oxygen delivery. Coronary artery disease and cardiomyopathic (enlarged heart) conditions result in a diminished stroke volume (i.e., the volume of blood ejected from the ventricles) and decreased pump effectiveness. Hemorrhage and dehydration decrease pump effectiveness by decreasing the amount of blood ejected from the ventricles, thereby reducing circulating blood volume. The four chambers of the heart fill with blood during diastole and empty during systole.

The myocardial (cardiac muscle) fibres have contractile properties that enable them to stretch during filling. In a healthy heart, this stretch is proportionally related to the strength of contraction. As the myocardium stretches, the strength of the subsequent contraction increases; this is known

as the Frank-Starling (Starling's) law of the heart. In the diseased heart, Starling's law does not apply because the stretch of the myocardium is beyond the heart's physiological limits. The subsequent contractile response results in insufficient ventricular ejection (volume), and blood begins to "back up" in the pulmonary (left heart failure) or systemic circulation (right heart failure).

Myocardial Blood Flow. To maintain adequate blood flow to the pulmonary and systemic circulation, myocardial blood flow must supply sufficient oxygen and nutrients to the myocardium itself. Blood flow through the heart is unidirectional. There are four heart valves that ensure this forward blood flow (see Figure 38-1). During ventricular diastole, the atrioventricular (mitral and tricuspid) valves open and blood flows from the higher-pressure atria into the relaxed ventricles. This represents S_1 , or the first heart sound. After ventricular filling, the systolic phase begins.

During the systolic phase, semilunar (aortic and pulmonic) valves open and blood flows from the ventricles into the aorta and pulmonary artery. Closure of aortic and pulmonic valves represents S_2 , or the second heart sound. Patients with valvular disease may have backflow or regurgitation of blood through the incompetent valve, causing a murmur that is heard on auscultation (see Chapter 31).

Coronary Artery Circulation. Blood in the atria and ventricles does not supply oxygen and nutrients to the myocardium itself. The coronary circulation is the branch of the systemic circulation that supplies the myocardium with oxygen and nutrients and removes waste. The coronary arteries fill during ventricular diastole (McCance & Huether, 2005). The right and left coronary arteries arise from the aorta just above and behind the aortic valve through openings called the coronary ostia (coronary openings). The left coronary artery, the most abundant blood supply, feeds the left ventricular myocardium, which is more muscular and does most of the heart's work (Box 38-1).

Figure 38-1 Schematic representation of blood flow through the heart. Arrows indicate direction of flow. **Source:** Lewis, S. L., Heitkemper, M. M., Dirksen, S. R., O'Brien, P. G., & Bucher, L. (2010). *Medical-surgical nursing in Canada: Assessment and management of clinical problems* (2nd Canadian ed., p. 802, Fig. 33-2). Toronto: Elsevier Canada.

BOX 38-1 Coronary Arteries

Right Coronary Artery

Right Atrium, Anterior Right Ventricle

Supplies

- Posterior aspect of septum (90% of population)
- Posterior papillary muscle
- Sinus and atrioventricular nodes (80%–90% of population)
- Inferior aspect of left ventricle

Left Coronary Arteries

Left Anterior Descending Artery

Supplies

- Anterior left ventricular wall
- Anterior interventricular septum (septal branches supply conduction system, bundle of His, and bundle branches)
- Anterior papillary muscle
- Left ventricular apex
- Right ventricle

Circumflex Artery

Supplies

- Left atrium
- Posterior surfaces of left ventricle
- Posterior aspects of septum

Systemic Circulation. The arteries and veins of the systemic circulation deliver nutrients and oxygen to and remove waste from the tissues. Oxygenated blood flows from the left ventricle by way of the aorta and into large systemic arteries. These arteries branch into smaller arteries, into arterioles, and finally into the smallest vessels, the capillaries. At the capillary level, the exchange of respiratory gases, nutrients, and wastes occurs, and the tissues are oxygenated. The waste products exit the capillary network by way of the venules that join to form veins. These veins form larger veins, which carry deoxygenated blood to the right side of the heart, where it is returned to pulmonary circulation.

Blood Flow Regulation. The amount of blood ejected from the left ventricle each minute is the **cardiac output**. The normal cardiac output is 4 to 6 L/minute in the healthy 68 kg adult at rest. The circulating volume of blood changes according to the oxygen and metabolic needs of the body. For example, during exercise, pregnancy, and fever, the cardiac output increases, but during sleep it decreases. Cardiac output is represented by the following formula:

$$\text{Cardiac output (CO)} = \text{Stroke volume (SV)} \times \text{Heart rate (HR)}$$

Cardiac output in the older adult may be affected by increased arterial wall tension and moderate myocardial hypertrophy due to an increased systolic blood pressure.

Cardiac index (CI) is the adequacy of the cardiac output for an individual. It takes into account the body surface area (BSA) of the patient. The CI is determined by dividing the cardiac output by the BSA. The normal range is 2.5 to 4 L/minute/m². Both cardiac output and the CI are measured with invasive pulmonary artery catheters.

Stroke volume is the amount of blood ejected from the left ventricle with each contraction. It can be affected by the amount of blood in the left ventricle at the end of diastole (preload), the resistance to left ventricular ejection (afterload), and myocardial contractility.

Preload is essentially the end-diastolic volume. The ventricles stretch when filling with blood. The more stretch on the ventricular muscle, the greater the contraction and the greater the stroke volume (Starling's law). In clinical situations, the preload and subsequent stroke volume can be manipulated by changing the amount of circulating blood volume. For example, in the patient with hemorrhagic shock, fluid therapy and replacement of blood increases volume, thus increasing the preload and cardiac output. If volume is not replaced, preload decreases, the cardiac output decreases, and, ultimately, the venous return to the right atrium decreases, further decreasing preload and cardiac output.

Afterload is the resistance to left ventricular ejection—the work that the heart must overcome to fully eject blood from the left ventricle. The diastolic aortic pressure is a good clinical measure of afterload. In a patient with an acute hypertensive crisis, the afterload is greater than normal, increasing the cardiac workload. Afterload in this situation can be manipulated by decreasing systemic blood pressure.

The measurement and monitoring of these cardiopulmonary hemodynamics is usually performed in critical care units. Some stepdown or special care units may also have the capability to measure and monitor hemodynamics.

Myocardial contractility also affects stroke volume and cardiac output. Poor contraction decreases the amount of blood ejected by the ventricles during each contraction. Drugs

Figure 38-2 Conduction system of the heart. AV, atrioventricular; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; SA, sinoatrial. **Source:** Lewis, S. M., Heitkemper, M. M., Dirksen, S. R., O'Brien, P. G., & Bucher, L. (2010). *Medical-surgical nursing in Canada: Assessment and management of clinical problems* (2nd Canadian ed., p. 803). Toronto: Elsevier Canada.

that can increase the force of myocardial contraction include digitalis preparations, epinephrine, and sympathomimetic drugs (drugs that mimic the effects of the sympathetic nervous system). Injury to the myocardial muscle, such as an acute myocardial infarction (AMI), can cause a decrease in myocardial contractility. The myocardium of the older adult is more rigid and slower in recovering its contractility (Meiner & Leuckenotte, 2006).

Heart rate affects blood flow because of the interaction between rate and diastolic filling time. With a sustained heart rate greater than 160 beats per minute, diastolic filling time decreases, decreasing stroke volume and cardiac output. The heart rate of the older adult is slow to increase under stress (Meiner & Leuckenotte, 2006).

Conduction System. The rhythmic relaxation and contraction of the atria and ventricles depend on continuous, organized transmission of electrical impulses. These impulses are generated and transmitted by way of the cardiac conduction system (Figure 38-2).

The heart's conduction system generates the necessary action potentials that conduct the impulses required to initiate the electrical chain of events resulting in the heartbeat. The autonomic nervous system influences the rate of impulse generation, the speed of transmission through the conductive pathway, and the strength of atrial and ventricular contractions. Sympathetic nerve fibres, which increase the rate of impulse generation and the speed of impulse transmission, innervate all parts of the atria and ventricles. The parasympathetic fibres originating from the vagus nerve decrease the rate and innervate all parts of the atria and ventricles, as well as the sinoatrial (SA) and atrioventricular (AV) nodes (McCance & Huether, 2005).

The conduction system originates with the SA node, the "pacemaker" of the heart. The SA node is in the right atrium next to the entrance of the superior vena cava. Impulses are initiated at the SA node at an intrinsic rate of 60 to 100 beats

Figure 38-3 Normal ECG waveform.

per minute. The resting adult rate is approximately 75 beats per minute.

The electrical impulses are then transmitted through the atria along intra-atrial pathways to the AV node. The AV node mediates impulses between the atria and the ventricles. The intrinsic rate of the normal AV node is 40 to 60 beats per minute. The AV node assists atrial emptying by delaying the impulse before transmitting it through the bundle of His and the ventricular Purkinje network. The intrinsic rate of the bundle of His and the ventricular Purkinje network is 20 to 40 beats per minute.

An **electrocardiogram (ECG)** reflects the electrical activity of the conduction system. An ECG monitors the regularity and path of the electrical impulse through the conduction system; however, it does not reflect muscular work of the heart. The normal sequence on the ECG is called **normal sinus rhythm (NSR)** (Figure 38-3).

NSR implies that the impulse originates at the SA node and follows the normal sequence through the conduction system. The P wave represents the electrical conduction through both atria. Atrial contraction follows the P wave. The PR interval represents the impulse travel time through the AV node, through the bundle of His, and to the Purkinje fibres. The normal length for the PR interval is 0.12 to 0.20 seconds. An increase in the time (i.e., >0.20 seconds) indicates that there is a block in the impulse transmission through the AV node; a decrease (i.e., <0.12 seconds) indicates the initiation of the electrical impulse from a source other than the SA node.

The QRS complex indicates that the electrical impulse has travelled through the ventricles. Normal QRS duration is 0.06 to 0.12 seconds. An increase in QRS duration indicates a delay in conduction time through the ventricles. Ventricular contraction usually follows the QRS complex.

The QT interval represents the time needed for ventricular depolarization and repolarization. The normal QT interval is 0.12 to 0.42 seconds. Changes in electrolyte values, such as in hypocalcemia or during therapy with drugs such as disopyramide, amiodarone, and theophylline (Theo-Dur), can increase the QT interval. Shortening of the QT interval occurs with digitalis therapy, hyperkalemia, and hypercalcemia.

Respiratory Physiology

Most cells in the body obtain their energy from chemical reactions involving oxygen and the elimination of carbon dioxide.

Figure 38-4 Structures of the pulmonary system. The circle denotes the alveoli. **Source:** Thompson, J. M., McFarland, G. K., Hirsch, J. E., Tucker, S. M., & Bowers, A. C. (Eds.). (1993). *Mosby's clinical nursing* (3rd ed.). St Louis, MO: Mosby-Year Book.

The exchange of respiratory gases occurs between environmental air and the blood (Figure 38-4). There are three steps in the process of oxygenation: ventilation, perfusion, and diffusion.

Structure and Function. Conditions or diseases that change the structure and function of the lung can alter respiration. The respiratory muscles, pleural space, lungs, and alveoli (Figure 38-5) are essential for ventilation, perfusion, and exchange of respiratory gases. Gases are moved into and out of the lungs through pressure changes. Intrapleural pressure is either negative or less than atmospheric pressure, which is 760 mm Hg at sea level. For air to flow into the lungs, intrapleural pressure must become more negative, setting up a pressure gradient between the atmosphere and the alveoli. The diaphragm and external intercostal muscles contract to create a negative pleural pressure and increase the size of the thorax for inspiration. Relaxation of the diaphragm and contraction of the internal intercostal muscles allows air from the lung to escape. The coordination of the respiratory muscles is essential for effective respiration and gas exchange. The lung transfers oxygen from the atmosphere into the alveoli, where the oxygen is exchanged for carbon dioxide. The alveoli transfer oxygen and carbon dioxide to and from the blood through the alveolar membrane.

Ventilation is the process of moving gases into and out of the lungs. Ventilation requires coordination of the muscular and elastic properties of the lung and thorax, as well as intact innervation. The major inspiratory muscle of respiration is the diaphragm. It is innervated by the phrenic nerve, which exits the spinal cord at the fourth cervical vertebra. Perfusion relates

Figure 38-5 Alveoli at the terminal end of the lower airway. **Source:** Thompson, J., M., McFarland, G. K., Hirsch, J. E., Tucker, S. M., & Bowers, A. C. (Eds.). (1993). *Mosby's clinical nursing* (3rd ed.). St Louis, MO: Mosby-Year Book.

to the ability of the cardiovascular system to pump oxygenated blood to the tissues and return deoxygenated blood to the lungs. Diffusion is responsible for moving the molecules from one area to another. For the exchange of respiratory gases to occur, the organs, nerves, and muscles of respiration must be intact and the central nervous system able to regulate the respiratory cycle.

Work of Breathing. Breathing is the effort required for expanding and contracting the lungs. In the healthy individual, breathing is quiet and accomplished with minimal effort. The amount of energy expended on breathing depends on the rate and depth of breathing, the ease with which the lungs can be expanded (compliance), and airway resistance (Jevon & Ewens, 2001).

Inspiration is an active process, stimulated by chemical receptors in the aorta. **Expiration** is a passive process that depends on the elastic-recoil properties of the lungs, requiring little or no muscle work. Elastic recoil is produced by elastic fibres in lung tissue and by surface tension in the fluid film lining the alveoli. Surfactant is a chemical produced in the lungs that maintains the surface tension of the alveoli and keeps them from collapsing. Patients with advanced chronic obstructive pulmonary disease (COPD) lose the elastic recoil of the lungs and thorax. As a result, the patient's work of breathing is increased. In addition, patients with certain pulmonary diseases can have decreased surfactant production and may, in turn, develop atelectasis.

Accessory muscles of respiration can increase lung volume during inspiration. Patients with COPD, especially emphysema, frequently use these muscles to increase lung volume. Prolonged use of the accessory muscles of respiration does not promote effective ventilation and causes fatigue. During assessment, observe elevation of the patient's clavicles during inspiration.

Compliance is the ability of the lungs to distend or expand in response to increased intra-alveolar pressure. Compliance is

decreased in diseases such as pulmonary edema, interstitial and pleural fibrosis, and congenital or traumatic structural abnormalities such as kyphosis or fractured ribs.

Airway resistance is the pressure difference between the mouth and the alveoli in relation to the rate of flow of inspired gas. Airway resistance can be increased by an airway obstruction, small airway disease (such as asthma), and tracheal edema. When resistance is increased, the amount of air traveling through the anatomical airways is decreased.

Decreased lung compliance, increased airway resistance, active expiration, or the use of accessory muscles increases the work of breathing, resulting in increased energy expenditure. To meet this expenditure, the body increases its metabolic rate, and the need for oxygen, as well as for the elimination of carbon dioxide, increases. This sequence is a vicious cycle for a patient with impaired ventilation, causing further deterioration of respiratory status and the ability to oxygenate adequately.

Lung Volumes and Capacities. Spirometry is used to measure the volume of air entering or leaving the lungs. Variations in lung volumes may be associated with health states such as pregnancy, exercise, obesity, or obstructive and restrictive conditions of the lungs. The amount of surfactant, degree of compliance, and strength of respiratory muscles can affect pressures and volumes within the lungs.

Pulmonary Circulation. The primary function of the pulmonary circulation is to move blood to and from the alveolo-capillary membrane in order for gas exchange to occur. The pulmonary circulation serves as a reservoir for blood so that the lung can increase its blood volume without large increases in pulmonary artery or venous pressures. The pulmonary circulation also acts as a filter, removing small thrombi before they can reach vital organs.

The pulmonary circulation begins at the pulmonary artery, which receives poorly oxygenated mixed venous blood from the right ventricle. Blood flow through this system depends on the pumping ability of the right ventricle, which has an output of approximately 4 to 6 L/minute. The flow continues from the pulmonary artery through the pulmonary arterioles to the pulmonary capillaries, where blood comes in contact with the alveolocapillary membrane and the exchange of respiratory gases occurs. The oxygen-rich blood then circulates through the pulmonary venules and pulmonary veins, returning to the left atrium.

Pressure and resistance within the pulmonary circulatory system is lower than that within the systemic circulatory system. The walls of the pulmonary vessels are thinner and contain less smooth muscle. The lung accepts the total cardiac output from the right ventricle and, except in cases of alveolar hypoxia or cor pulmonale, does not direct blood flow from one region to another. **Cor pulmonale** is a condition in which the right ventricle is enlarged, secondary to diseases of the lung, thorax, or pulmonary circulation.

Respiratory Gas Exchange. Respiratory gases are exchanged in the alveoli and the capillaries of the body tissues. Oxygen is transferred from the lungs to the blood, and carbon dioxide is transferred from the blood to the alveoli to be exhaled as a waste product. At the tissue level, oxygen is transferred from the blood to tissues, and carbon dioxide is transferred from tissues to the blood to return to the alveoli and be exhaled. This transfer is dependent on the process of diffusion.

Diffusion is the movement of molecules from an area of higher concentration to an area of lower concentration.

Diffusion of respiratory gases occurs at the alveolocapillary membrane, and the rate of diffusion can be affected by the thickness of the membrane. Increased thickness of the membrane impedes diffusion because gases take longer to transfer across. Patients with pulmonary edema, pulmonary infiltrates, or a pulmonary effusion have an increased thickness of the alveolocapillary membrane, resulting in slowed diffusion, slowed exchange of respiratory gases, and impaired delivery of oxygen to tissues. The surface area of the membrane can be altered as a result of chronic disease (e.g., emphysema), acute disease (e.g., pneumothorax), or surgical process (e.g., lobectomy). The alveolocapillary membrane can be destroyed or may thicken, changing the rate of diffusion. When fewer alveoli are functioning, the surface area is decreased.

Oxygen Transport. The oxygen transport system consists of the lungs and cardiovascular system. Delivery depends on the amount of oxygen entering the lungs (ventilation), blood flow to the lungs and tissues (perfusion), rate of diffusion, and oxygen-carrying capacity. The capacity of the blood to carry oxygen is influenced by the amount of dissolved oxygen in the plasma, amount of hemoglobin, and tendency of hemoglobin to bind with oxygen. Only a relatively small amount of required oxygen, less than 1%, is dissolved in the plasma. Most oxygen is transported by hemoglobin, which serves as a carrier for oxygen and carbon dioxide. The hemoglobin molecule combines with oxygen to form oxyhemoglobin. The formation of oxyhemoglobin is easily reversible, allowing hemoglobin and oxygen to dissociate, which frees oxygen to enter tissues.

Carbon Dioxide Transport. Carbon dioxide diffuses into red blood cells and is rapidly hydrated into carbonic acid (H_2CO_3) because of the presence of carbonic anhydrase. The carbonic acid then dissociates into hydrogen (H^+) and bicarbonate (HCO_3^-) ions. The hydrogen ion is buffered by hemoglobin, and the HCO_3^- diffuses into the plasma (see Chapter 39). In addition, some of the carbon dioxide in red blood cells reacts with amino acid groups, forming carbamino compounds. This reaction can occur rapidly without the presence of an enzyme. Reduced hemoglobin (deoxyhemoglobin) can combine with carbon dioxide more easily than oxyhemoglobin, thus venous blood transports most of the carbon dioxide.

Regulation of Respiration. Regulation of respiration is necessary to ensure sufficient oxygen intake and carbon dioxide elimination to meet the body's demands (e.g., during exercise, infection, or pregnancy). Neural and chemical regulators control the process of respiration. Neural regulation includes the central nervous system control of respiratory rate, depth, and rhythm. Chemical regulation involves the influence of chemicals such as carbon dioxide and hydrogen ions on the rate and depth of respiration (Box 38-2).

Factors Affecting Oxygenation

Adequacy of circulation, ventilation, perfusion, and transport of respiratory gases to the tissues is influenced by four types of factors: (1) physiological, (2) developmental, (3) lifestyle, and (4) environmental. Developmental, lifestyle, and environmental factors will be presented in a later section.

Physiological Factors. Any condition that affects cardiopulmonary functioning directly affects the body's ability to meet oxygen demands. The general classifications of cardiac disorders are disturbances in conduction, impaired valvular function, myocardial hypoxia, cardiomyopathic conditions, and peripheral tissue hypoxia. Respiratory disorders include hyperventilation, hypoventilation, and hypoxia.

► BOX 38-2

Physiological Processes of Oxygenation

Neural Regulation

Maintains rhythm and depth of respiration and balance between inspiration and expiration.

Cerebral Cortex

Voluntary control of respiration delivers impulses to the respiratory motor neurons by way of the spinal cord; accommodates speaking, eating, and swimming.

Medulla Oblongata

Automatic control of respiration occurs continuously.

Chemical Regulation

Maintains appropriate rate and depth of respirations according to changes in the blood's carbon dioxide (CO_2), oxygen (O_2), and hydrogen ion (H^+) concentration.

Chemoreceptors

Located in the medulla, aortic body, and carotid body. Changes in chemical content of O_2 , CO_2 , and H^+ stimulate chemoreceptors, which in turn stimulate neural regulators to adjust the rate and depth of ventilation to maintain normal arterial blood gas levels. Chemical regulation can occur during physical exercise and with some illnesses. It is a short-term adaptive mechanism.

► TABLE 38-1

Physiological Processes Affecting Oxygenation

Process	Effect on Oxygenation
Anemia	Decreases oxygen-carrying capacity of blood
Toxic inhalant	Decreases oxygen-carrying capacity of blood
Airway obstruction	Limits delivery of inspired oxygen to alveoli
High altitude	Atmospheric oxygen concentration is lower and inspiratory oxygen concentration decreases
Fever	Increases metabolic rate and tissue oxygen demand
Decreased chest wall motion (e.g., from musculoskeletal impairments)	Prevents lowering of diaphragm and reduces anteroposterior diameter of thorax on inspiration, reducing volume of air inspired

Other physiological processes affecting a patient's oxygenation are alterations that affect the oxygen-carrying capacity of blood, such as anemia, increases in the body's metabolic demands (e.g., pregnancy, fever, infection), and alterations that affect chest wall movement or the central nervous system (Table 38-1).

Decreased Oxygen-Carrying Capacity. Hemoglobin carries most of the oxygen to tissues. Anemia and inhalation of toxic substances decrease the oxygen-carrying capacity of blood by reducing the amount of available hemoglobin to transport oxygen. **Anemia**, a hemoglobin level lower than normal, is a result of decreased hemoglobin production, increased red blood cell destruction, blood loss, or a combination of these factors. Patients will have complaints of fatigue,

decreased activity tolerance, and increased breathlessness, as well as pallor (especially seen in the conjunctiva of the eye) and an increased heart rate.

Carbon monoxide is the most common toxic inhalant that decreases the oxygen-carrying capacity of blood. The affinity for hemoglobin to bind with carbon monoxide is greater than 200 times its affinity to bind with oxygen, creating a functional anemia. Because of the bond's strength, carbon monoxide is not easily dissociated from hemoglobin, making the hemoglobin unavailable for oxygen transport.

Decreased Inspired Oxygen Concentration. When the concentration of inspired oxygen declines, the blood has less oxygen-carrying capacity. Decreases in the fraction of inspired oxygen concentration (FiO_2) can be caused by an upper or lower airway obstruction limiting delivery of inspired oxygen to alveoli; decreased environmental oxygen, such as at high altitudes; or decreased inspiration as a result of an incorrect oxygen concentration setting on respiratory therapy equipment.

Hypovolemia. Hypovolemia is caused by conditions such as shock and severe dehydration resulting from extracellular fluid loss and reduced circulating blood volume. With a significant fluid loss, the body tries to adapt by increasing the heart rate and peripheral vasoconstriction to increase the volume of blood returned to the heart and, in turn, increase the cardiac output.

Increased Metabolic Rate. Increased metabolic activity causes increased oxygen demand. When body systems are unable to meet this increased demand, the level of oxygenation declines. An increased metabolic rate is a normal physiological response to pregnancy, wound healing, and exercise because the body is building tissue. Most people can meet the increased oxygen demand and do not display signs of oxygen deprivation. Fever increases the tissues' need for oxygen, and as a result, carbon dioxide production also increases.

If the febrile state persists, the metabolic rate remains high and the body begins to break down protein stores, resulting in muscle wasting and decreased muscle mass. Respiratory muscles such as the diaphragm and intercostal muscles are also wasted. The body attempts to adapt to the increased carbon dioxide levels by increasing the rate and depth of respiration. The patient's work of breathing increases, and the patient will eventually display signs and symptoms of hypoxemia. Patients with pulmonary diseases are at greater risk for hypoxemia and **hypercapnia** (a greater than normal amount of carbon dioxide in the blood). Assessment findings include an increased rate and depth of respiration, use of the accessory muscles of respiration, pursed-lip breathing, and decreased activity tolerance.

Conditions Affecting Chest Wall Movement. Any condition that reduces chest wall movement can result in decreased ventilation. If the diaphragm cannot fully descend with breathing, the volume of inspired air decreases, and less oxygen is delivered to the alveoli and subsequently to tissues.

Pregnancy. As the fetus grows during pregnancy, the greater size of the uterus pushes abdominal contents upward against the diaphragm. In the last trimester of pregnancy, the inspiratory capacity declines, resulting in dyspnea on exertion and increased fatigue.

Obesity. Morbidly obese patients have reduced lung volumes as a result of the heaviness of the lower thorax and abdomen, particularly when in the recumbent and supine

positions. These patients have a reduction in compliance as a result of encroachment of the abdomen into the chest, increased work of breathing, and decreased lung volumes, and they may experience fatigue and have carbon dioxide retention. In some patients, an obesity-hypoventilation syndrome develops in which oxygenation is decreased and carbon dioxide is retained, resulting in daytime sleepiness. Morbidly obese patients may also develop obstructive sleep apnea, characterized by excessive daytime somnolence and loud snoring and apneic periods during sleep. The obese patient is also susceptible to pneumonia after surgery or an upper respiratory tract infection because the lungs cannot fully expand and pulmonary secretions are not mobilized in the lower lobes.

Musculoskeletal Abnormalities. Musculoskeletal impairments in the thoracic region reduce oxygenation. Such impairments may result from abnormal structural configurations, trauma, muscular diseases, and diseases of the central nervous system. Abnormal structural configurations impairing oxygenation include those that affect the rib cage, such as pectus excavatum (an indentation of the lower sternum), and those that affect the vertebral column, such as kyphosis, lordosis, or scoliosis.

Trauma. The person with multiple rib fractures can develop a flail chest, a condition in which fractures cause instability in part of the chest wall. The unstable chest wall allows the lung underlying the injured area to contract on inspiration and bulge on expiration, resulting in hypoxia. Chest wall or upper abdominal incisions may also decrease chest wall movement as the patient uses shallow respirations to minimize chest wall movement to avoid pain. Excessive or high doses of narcotic analgesics may depress the respiratory centre, further decreasing respiratory rate and chest wall expansion.

Neuromuscular Diseases. Diseases such as muscular dystrophy affect oxygenation of tissues by decreasing the patient's ability to expand and contract the chest wall. Ventilation is impaired, and atelectasis, hypercapnia, and hypoxemia can occur. Myasthenia gravis, Guillain-Barré syndrome, and poliomyelitis affect respiratory functioning and result in hypoventilation. Myasthenia gravis interferes with normal transmission of impulses from nerves to muscles, involving the whole body, including muscles of respiration. Guillain-Barré syndrome and poliomyelitis cause inflammation and paralysis of muscle groups. Guillain-Barré syndrome usually results in an ascending pattern of paralysis. Respiratory muscles become paralyzed as paralysis ascends to the thoracic region. Poliomyelitis may lead to general or local paralysis. Both disorders may reverse, but poliomyelitis usually results in more residual paralysis.

Central Nervous System Alterations. Diseases or trauma involving the medulla oblongata and spinal cord may result in impaired respiration. When the medulla oblongata is affected, neural regulation of respiration is damaged and abnormal breathing patterns may develop. If the phrenic nerve is damaged, the diaphragm may not descend, thus reducing inspiratory lung volumes and causing hypoxemia. Cervical trauma at C3 to C5 can result in paralysis of the phrenic nerve. Spinal cord trauma below the fifth cervical vertebra usually leaves the phrenic nerve intact but damages nerves that innervate the intercostal muscles, preventing anteroposterior chest expansion.

Influences of Chronic Disease. Oxygenation can be decreased as a direct consequence of chronic disease. It can also be decreased as a secondary effect, as with anemia. The

physiological response to chronic hypoxemia is the development of a secondary polycythemia (increase in red blood cells). This adaptive response is the body's attempt to increase the amount of circulating hemoglobin to increase the available oxygen-binding sites.

Alterations in Cardiac Functioning

Illnesses and conditions that affect cardiac rhythm, strength of contraction, blood flow through the chambers, myocardial blood flow, and peripheral circulation cause alterations in cardiac functioning. Older adults experience alterations in cardiac function due to calcification of the conduction pathways, thicker and stiffer heart valves from lipid accumulation and fibrosis, and a decrease in the number of pacemaker cells in the SA node (Meiner & Leuckenotte, 2006).

Disturbances in Conduction. Some disturbances in conduction are a result of electrical impulses that do not originate from the SA node. These rhythm disturbances are called **dysrhythmias**, meaning a deviation from the normal sinus heart rhythm (Table 38-2). Dysrhythmias may occur as a primary conduction disturbance; as a response to ischemia, valvular abnormality, anxiety, or drug toxicity; as a result of caffeine, alcohol, or tobacco use; or as a complication of acid-base or electrolyte imbalance (see Chapter 39). Such disturbances may be life-threatening and require treatment with medication or defibrillation (Box 38-3).

Dysrhythmias are classified by cardiac response and site of impulse origin. Cardiac response can be tachycardiac (>100 beats/minute), bradycardiac (<60 beats/minute), a premature (early) beat, or a blocked (delayed or absent) beat. Tachydysrhythmias and bradydysrhythmias can lower cardiac output and blood pressure. Tachydysrhythmias reduce cardiac output by decreasing diastolic filling time. Bradydysrhythmias lower cardiac output because of the decreased heart rate.

Atrial fibrillation is a common type of dysrhythmia in older adults. The electrical impulse in the atria is chaotic and originates from multiple sites. The rhythm is irregular because of the multiple pacemaker sites and the unpredictable conduction to the ventricles. The QRS complex is normal; however, it occurs at irregular intervals. Atrial fibrillation is often described as an irregularly irregular rhythm.

Abnormal impulses originating above the ventricles are referred to as supraventricular dysrhythmias. The abnormality on the waveform is the configuration and placement of the P wave. Ventricular conduction usually remains normal, and a normal QRS complex is observed.

Ventricular dysrhythmias represent an ectopic site of impulse formation within the ventricles. It is ectopic in that the impulse originates in the ventricle, not the SA node. The

configuration of the QRS complex is usually widened and bizarre. P waves may or may not be present; often they are buried in the QRS complex. **Ventricular tachycardia** and **ventricular fibrillation** are life-threatening rhythms that require immediate intervention. Ventricular tachycardia is considered a life-threatening dysrhythmia because of the decreased cardiac output and the potential to deteriorate into ventricular fibrillation (American Heart Association [AHA], 2005).

Asystole is a lethal rhythm associated with no apparent electrical activity. The patient has no cardiac output and thus no palpable pulse. If the patient is on a cardiac monitor, the lack of electrical activity is noted by an absent rhythm. Asystole can occur as a primary event, it may follow ventricular fibrillation, or it can occur in patients with complete heart block. Asystole must be treated immediately.

Altered Cardiac Output. Failure of the myocardium to eject sufficient volume to the systemic and pulmonary circulations can result in heart failure. Depending on the severity of symptoms, heart dysfunction, age, and other factors, heart failure can be associated with an annual mortality rate of 5 to 50% (Arnold et al., 2006, p. 24). Primary coronary artery disease, cardiomyopathic conditions, valvular disorders, and pulmonary disease lead to myocardial pump failure.

Left-Sided Heart Failure. Left-sided heart failure is an abnormal condition characterized by impaired functioning of the left ventricle as a result of elevated pressures and pulmonary congestion. If left ventricular failure is significant, the amount of blood ejected from the left ventricle drops greatly, resulting in decreased cardiac output. Assessment findings may include decreased activity tolerance, breathlessness, dizziness, and confusion as a result of tissue hypoxia from the diminished cardiac output. As the left ventricle continues to fail, blood begins to pool in the pulmonary circulation, causing pulmonary congestion. Clinical findings include crackles on auscultation, hypoxia, shortness of breath on exertion and often at rest, cough, and paroxysmal nocturnal dyspnea.

Right-Sided Heart Failure. Right-sided heart failure results from impaired functioning of the right ventricle characterized by venous congestion in the systemic circulation. Right-sided heart failure more commonly results from pulmonary disease or from long-term left-sided failure. The primary pathological factor in right-sided failure is elevated pulmonary vascular resistance (PVR). As the PVR continues to rise, the right ventricle must generate more work, and the oxygen demand of the heart increases. As the failure continues, the amount of blood ejected from the right ventricle declines, and blood begins to "back up" in the systemic circulation. Clinically, the patient has weight gain, distended neck veins, hepatomegaly and splenomegaly, and dependent peripheral edema.

Impaired Valvular Function. Valvular heart disease is an acquired or congenital disorder of a cardiac valve characterized by stenosis and obstructed blood flow or valvular degeneration and regurgitation of blood. When stenosis occurs in the semilunar valves (aortic and pulmonic valves), the adjacent ventricles must work harder to move the ventricular volume beyond the stenotic valve. Over time, the stenosis can cause the ventricle to hypertrophy (enlarge), and if the condition is left untreated, left- or right-sided heart failure can occur. If stenosis occurs in the atrioventricular valves (mitral and tricuspid valves), the atrial pressure rises, causing the atria to hypertrophy. When regurgitation occurs, there is a backflow of blood into an adjacent chamber. For example, in mitral regurgitation, the mitral leaflets do not close completely. When the

► BOX 38-3

Automated External Defibrillator (AED)

- An automated external defibrillator is a device used to administer an electrical shock through the chest wall to the heart.
- Built-in computers assess the victim's heart rhythm and determine if defibrillation is needed.
- The AED delivers a shock to the victim.
- It can be used by nonmedical personnel.
- It is used to strengthen the chain of survival. Every minute of a sudden cardiac arrest without defibrillation decreases the survival rate by 7%–10% (Link et al., 2010, p. S706).

► **TABLE 38-2** Common Basic Cardiac Dysrhythmias

Rhythm Characteristics and Etiology

Sinus Tachycardia

Regular rhythm, rate 100–180 beats/minute (higher in infants), normal P wave, normal QRS complex.

Rate increase may be a normal response to exercise, emotion, or stressors such as pain, fever, pump failure, hyperthyroidism, and certain drugs (e.g., caffeine, nitrates, epinephrine, nicotine).

Sinus Bradycardia

Regular rhythm, rate <60 beats/minute, normal P wave, normal PR interval, normal QRS complex.

Rate decrease may be a normal response to sleep or in well-conditioned athlete; abnormal drops in rate may be caused by diminished blood flow to SA node, vagal stimulation, hypothyroidism, increased intracranial pressure, or pharmacological agents (e.g., digoxin, propranolol, quinidine, procainamide).

Atrial Fibrillation (A-fib)

Chaotic, irregular atrial activity resulting in an irregular ventricular response. No identifiable P waves. Irregular ventricular response resulting in an irregular cardiac rate and rhythm. The rate is determined by the conduction of the multiple atrial impulses across the AV node.

A-fib is caused by aging, calcification of the SA node, or changes in myocardial blood supply.

Ventricular Tachycardia

Rhythm slightly irregular, rate 100–200 beats/minute, P wave absent, PR interval absent, QRS complex wide and bizarre, >0.12 seconds.

Caused by changes in the normal pacemaker of the heart, such as decrease in blood flow, ischemia, or embolus.

Clinical Significance and Management

Patient with damaged heart may not be able to sustain increased myocardial oxygen consumption by increased heart rate.

Correct underlying causes; discontinue drugs producing the side effect.

No clinical significance unless associated with signs and symptoms of reduced cardiac output such as dizziness or syncope or presence of chest pain.

Bradycardia with hypotension and decreased cardiac output is treated with atropine; a pacemaker may be required.

There is a loss of the atrial kick (portion of the cardiac output squeezed in the ventricles with a coordinated atrial contraction), pooling of blood in the atria, and development of microemboli. The patient may complain of fatigue, a fluttering in the chest, or shortness of breath if the ventricular response is rapid. A-fib is a commonly occurring dysrhythmia in the aging and older adult. Anticoagulants such as warfarin (Coumadin) may be used to reduce the risk of stroke. Warfarin is prescribed on the basis of the international normalized ratio (INR) and thus dose adjustments are based on daily INR results.

Results in a decreased cardiac output due to decreased ventricular filling time; may lead to severe hypotension and loss of pulse and consciousness.

If pulseless, interventions may include defibrillation, cardiopulmonary resuscitation (CPR), epinephrine, and amiodarone (Neumar et al., 2010, p. S736).

► **TABLE 38-2** Common Basic Cardiac Dysrhythmias—cont'd

Rhythm Characteristics and Etiology

Ventricular Fibrillation

Uncoordinated electrical activity. No identifiable P, QRS, or T wave. Causes include sudden cardiac death, electrical shock, acute myocardial infarction, drowning, or trauma.

Clinical Significance and Management

Acute loss of pulse and respiration. Defibrillation, CPR, and a vasopressor may be used as initial interventions for ventricular fibrillation (Neumar et al., 2010, p. S736).

The 2010 American Heart Association Guidelines for CPR and Emergency Cardiovascular Care recommend the establishment of automated external defibrillator programs in public locations where there is a relatively high likelihood of witnessed cardiac arrest (AHA, 2010; Link et al., 2010); see Box 38-3).

Asystole

Classically referred to as a “flat line.” There are no electrical impulses and therefore no QRS complex, no contraction, and no cardiac output. Possible causes are hypoxia, hyperkalemia and hypokalemia, pre-existing acidosis, drug overdose, and hypothermia.

The unresponsive patient will have no pulse, blood pressure, or respirations. The management of asystole consists of CPR, administering epinephrine, and correction of the underlying cause (Neumar et al., 2010, p. S736).

Adapted from Canobbio, M. M. (1990). *Cardiovascular disorders*. St Louis, MO: Mosby. Diagram of “sinus tachycardia” from Ignatavicius, D. D., & Workman, M. L. (2006). *Medical-surgical nursing: Critical thinking for collaborative care* (5th ed., p. 718). Philadelphia: W. B. Saunders. Diagram of “asystole” from Aehlert, B. (2011). *ECGs made easy* (4th ed., p. 172, Fig. 6-19). St Louis, MO: Mosby.

ventricles contract, blood escapes back into the atria, causing a murmur, or “whooshing” sound (see Chapter 31).

Myocardial Ischemia. Myocardial ischemia results when the supply of blood to the myocardium from the coronary arteries is insufficient to meet the oxygen demands of the organ. Common manifestations of this ischemia include angina pectoris, myocardial infarction, and acute coronary syndrome.

Angina Pectoris. Angina pectoris is usually a transient imbalance between myocardial oxygen supply and demand. The condition results in chest pain that is aching, sharp, tingling, or burning, or that feels like pressure. The chest pain may be left-sided or substernal and may radiate to the left or both arms, and to the jaw, neck, and back. In some patients, anginal pain may not radiate. The pain can last from 1 to 15 minutes. Patients report that pain is often precipitated by activities that increase myocardial oxygen demand (e.g., exercise, anxiety, or stress). The pain is usually relieved with rest and coronary vasodilators, the most common being a nitroglycerine preparation.

Myocardial Infarction. Myocardial infarction (MI) results from sudden decreases in coronary blood flow or an increase in myocardial oxygen demand without adequate coronary perfusion. Infarction occurs because of ischemia (which is reversible) and necrosis (which is not reversible) of myocardial tissue.

Chest pain associated with MI in men is usually described as crushing, squeezing, or stabbing. The pain may be retrosternal and left precordial, and it may radiate down the left arm to the neck, jaws, teeth, epigastric area, and back. The pain occurs at rest or on exertion, lasts more than 30 minutes, and is unrelieved by rest, position change, or sublingual nitroglycerine administration.

Current research indicates that there is a significant difference between men and women with regard to coronary artery disease. Women and men do not present the same type of symptoms (Chambers et al., 2007). The most common initial symptom in women is angina. However, women may also present with atypical symptoms such as fatigue, “indigestion,” vasospasm, shortness of breath, or back or jaw pain (Denke, 2001; Shaw et al., 2006). Compared to men, women tend to have fewer Q waves and ST-segment changes with chest pain.

Acute Coronary Syndrome. Acute coronary syndrome (ACS) includes unstable angina, non-ST-segment elevation MI, and ST-segment elevation MI. There is an imbalance in the oxygen supply and demand to the myocardium. Causes include nonocclusive thrombus on pre-existing plaque, coronary vasospasm, arterial narrowing from atherosclerosis, inflammation or infection, and secondary unstable angina from anemia, fever, or hypoxemia (Granger & Miller, 2001). Symptoms may not be constant and may present atypically.

Patients with classic AMI symptoms are more easily identified. Intermediate risk factors for ACS include male gender, age greater than 70 years with diabetes mellitus, extracardiac vascular disease, fixed Q waves, and previous abnormal ST segment and T-wave changes (Granger & Miller, 2001).

Alterations in Respiratory Functioning

Illnesses and conditions that affect ventilation or oxygen transport cause alterations in respiratory functioning. The three primary alterations are hyperventilation, hypoventilation, and hypoxia.

The goal of ventilation is to produce a normal arterial carbon dioxide tension (PaCO_2) between 35 and 45 mm Hg and maintain a normal arterial oxygen tension (PaO_2) between 80 and 100 mm Hg. Hyperventilation and hypoventilation refer to alveolar ventilation and not to the patient's respiratory rate. Arterial oxygen levels can be monitored using a noninvasive oxygen saturation monitor. The normal range is 95% to 100%. Hypoxia refers to a decrease in the amount of arterial oxygen.

Hyperventilation. Hyperventilation is a state of ventilation in excess of that required to eliminate the normal venous carbon dioxide produced by cellular metabolism. Anxiety, infections, drugs, or an acid–base imbalance can induce hyperventilation, as well as hypoxia associated with pulmonary embolus or shock. Acute anxiety can lead to hyperventilation and may cause loss of consciousness from excess carbon dioxide exhalation. Fever can cause hyperventilation. As a patient's body temperature increases, there is an increase in the metabolic rate, thereby increasing carbon dioxide production. The clinical response is an increased rate and depth of respiration.

Hyperventilation may also be chemically induced. Salicylate (aspirin) poisoning causes excessive stimulation of the respiratory centre as the body attempts to compensate for excess carbon dioxide. Amphetamines also increase ventilation by raising carbon dioxide production. Hyperventilation can also occur as the body tries to compensate for metabolic acidosis by producing a respiratory alkalosis. For example, the diabetic patient who has gone into diabetic ketoacidosis is producing large amounts of metabolic acids. The respiratory system tries to correct the acid–base balance by overbreathing. Ventilation increases to reduce the amount of carbon dioxide available to form carbonic acid (see Chapter 39). Hemoglobin does not release oxygen to tissues as readily, and tissue hypoxia results. As symptoms worsen, the patient may become more agitated, which further increases the respiratory rate and can result in respiratory alkalosis.

Hypoventilation. Hypoventilation occurs when alveolar ventilation is inadequate to meet the body's oxygen demand or to eliminate sufficient carbon dioxide. As alveolar ventilation decreases, PaCO_2 is elevated. Severe atelectasis can produce hypoventilation. **Atelectasis** is a collapse of the alveoli that prevents normal respiratory exchange of oxygen and carbon dioxide. As alveoli collapse, less of the lung can be ventilated and hypoventilation occurs.

In patients with COPD, the inappropriate administration of excessive oxygen can result in hypoventilation. These patients have adapted to a high carbon dioxide level, and their carbon dioxide–sensitive chemoreceptors are essentially not functioning. Their stimulus to breathe is a decreased PaO_2 . If excessive oxygen is administered, the oxygen requirement is satisfied and the stimulus to breathe is negated. High concentrations of

oxygen (e.g., >24%–28% [1–3 L/minute]) prevent the PaO_2 from falling and obliterate the stimulus to breathe, resulting in hypoventilation. The excessive retention of carbon dioxide may lead to respiratory arrest.

Signs and symptoms of hypoventilation include mental status changes, dysrhythmias, and potential cardiac arrest. Treatment requires improving tissue oxygenation, restoring ventilatory function, treating the underlying cause of the hypoventilation, and achieving acid–base balance. If untreated, the patient's status can rapidly decline, leading to convulsions, unconsciousness, and death.

Hypoxia. Hypoxia is inadequate tissue oxygenation at the cellular level. This can result from a deficiency in oxygen delivery or oxygen utilization at the cellular level. Hypoxia can be caused by (a) a decreased hemoglobin level and lowered oxygen-carrying capacity of the blood; (b) a diminished concentration of inspired oxygen, which may occur at high altitudes; (c) the inability of the tissues to extract oxygen from the blood, as with cyanide poisoning; (d) decreased diffusion of oxygen from the alveoli to the blood, as in pneumonia; (e) poor tissue perfusion with oxygenated blood, as with shock; and (f) impaired ventilation, as with multiple rib fractures or chest trauma.

The clinical signs and symptoms of hypoxia include apprehension, restlessness, inability to concentrate, declining level of consciousness, dizziness, and behavioural changes. The patient with hypoxia is unable to lie down and appears fatigued and agitated. Vital sign changes include an increased pulse rate and increased rate and depth of respiration. The patient with a narcotic overdose, such as a heroin overdose, may display signs of hypoventilation. During early stages of hypoxia, the blood pressure is elevated unless the condition is caused by shock. As the hypoxia worsens, the respiratory rate may decline as a result of respiratory muscle fatigue.

Cyanosis, or blue discolouration of the skin and mucous membranes caused by the presence of desaturated hemoglobin in capillaries, is a late sign of hypoxia. The presence or absence of cyanosis is not a reliable measure of oxygenation status. Central cyanosis, observed in the tongue, soft palate, and conjunctiva of the eye, where blood flow is high, indicates hypoxemia. Peripheral cyanosis, seen in the extremities, nail beds, and earlobes, is often a result of vasoconstriction and stagnant blood flow. Hypoxia is a life-threatening condition. Untreated, it can produce cardiac dysrhythmias that result in death. Hypoxia is managed by administration of oxygen and treatment of the underlying cause, such as airway obstruction.

Nursing Knowledge Base

Developmental Factors

The developmental stage of the patient and the normal aging process can affect tissue oxygenation.

Infants and Toddlers. Infants and toddlers are at risk for upper respiratory tract infections as a result of frequent exposure to other children and exposure to second-hand smoke. In addition, during the teething process, some infants develop nasal congestion, which encourages bacterial growth and increases the potential for respiratory tract infection. Upper respiratory tract infections are usually not dangerous, and infants or toddlers recover with little difficulty.

School-Aged Children and Adolescents. School-aged children and adolescents are exposed to respiratory infections and respiratory risk factors such as second-hand smoke

* BOX 38-4 FOCUS ON OLDER ADULTS

- The tuberculin skin test is an unreliable indicator of tuberculosis in older patients. They frequently display false-positive or false-negative skin test reactions.
- Older patients are at an increased risk for reactivation of dormant organisms that have been present for decades, as a result of age-related changes in the immune system.
- The standard 5-TU Mantoux test is given and repeated or repeated with the 250-TU strength to create a booster effect.
- If the older patient has a positive reaction, a complete history is necessary to determine any risk factors.
- Older adults have more atypical signs and symptoms of coronary artery disease (Meiner & Leuckenotte, 2006).
- The incidence of atrial fibrillation increases with age and is the leading contributing factor for stroke in the older adult (Meiner & Leuckenotte, 2006).
- Mental status changes are often the first signs of respiratory problems and may include forgetfulness and irritability.
- Older adults may not complain of dyspnea until it affects the activities of daily living that are important to them.
- Changes in the older adult's cough mechanism may lead to retention of pulmonary secretions, airway plugging, and atelectasis, if cough suppressants are not used with caution.

and cigarette smoking. A healthy child usually does not have adverse pulmonary effects from respiratory infections. A person who starts smoking in adolescence and continues to smoke into middle age, however, has an increased risk for cardiopulmonary disease and lung cancer.

Young and Middle-Aged Adults. Young and middle-aged adults are exposed to multiple cardiopulmonary risk factors: an unhealthy diet, lack of exercise, stress, over-the-counter and prescription drugs not used as intended, illegal drugs, and smoking. By reducing these modifiable factors patients may decrease their risk for cardiac or pulmonary diseases. During youth and middle age, lifelong habits and lifestyles are established. It is thus important to help these patients make good choices and informed decisions about the rest of their lives and their health care practices.

Older Adults. The cardiac and respiratory systems undergo changes throughout the aging process (Box 38-4). The changes are associated with calcification of the heart valves, SA node, and costal cartilages. The arterial system develops atherosclerotic plaques. Osteoporosis leads to changes in the size and shape of the thorax.

The trachea and large bronchi become enlarged from calcification of the airways. The alveoli enlarge, decreasing the surface area available for gas exchange. The number of functional cilia is reduced, causing a decrease in the effectiveness of the cough mechanism, putting the older adult at increased risk for respiratory infections (Meiner & Leuckenotte, 2006). Ventilation and transfer of respiratory gases decline with age because the lungs are unable to expand fully, leading to lower oxygenation levels.

Lifestyle Risk Factors

Lifestyle modifications that influence cardiopulmonary functioning are frequently difficult because a patient is being asked to change a habit or behaviour that may be enjoyed, such as

* BOX 38-5 FOCUS ON PRIMARY HEALTH CARE

Positive Lifestyle Practices for Cardiopulmonary Health Promotion

As part of a primary health care focus, it is important to educate young to older adults about the following lifestyle practices that promote cardiopulmonary health:

- Maintain ideal body weight.
- Eat a low-fat, low-salt, calorie-appropriate diet.
- Engage in regular aerobic exercise one hour daily.
- Use a filter mask when exposed to occupational hazards.
- Use stress-reduction techniques.
- Reduce exposure to secondary infections.
- Do not smoke.
- Avoid second-hand smoke and other pollutants.
- Have annual visits with a health care provider.
- Monitor blood pressure.
- Monitor cholesterol and triglyceride levels.
- Request an annual influenza vaccine, especially if at risk for the development of influenza.
- Request a pneumococcal vaccine, if appropriate.

cigarette smoking or eating certain foods; however, these changes can be achieved with encouragement, support, and time (Box 38-5). Risk factor modification is important and includes smoking cessation, weight reduction, a low-cholesterol and low-sodium diet, management of hypertension, and moderate exercise. Although it may be difficult to get older adults to change long-term behaviour, developing healthy behaviours can slow or halt the progression of their cardiopulmonary disease (Meiner & Leuckenotte, 2006).

Poor Nutrition. Nutrition affects cardiopulmonary function in several ways. Severe obesity decreases lung expansion, and the increased body weight increases oxygen demands to meet metabolic needs. The malnourished patient may experience respiratory muscle wasting, resulting in decreased muscle strength and respiratory excursion. Cough efficiency is reduced secondary to respiratory muscle weakness, putting the patient at risk for retention of pulmonary secretions. Diets high in fat increase cholesterol and atherogenesis in the coronary arteries.

Patients who are morbidly obese, malnourished, or both are at risk for anemia. Diets high in carbohydrates may play a role in increasing the carbon dioxide load for patients with carbon dioxide retention. As carbohydrates are metabolized, an increased load of carbon dioxide is created and excreted via the lungs.

Dietary sodium reduction could eliminate hypertension for over a million Canadians (Joffres et al., 2007, p. 441). Diets high in potassium may prevent hypertension and help improve control in patients with hypertension. A 2000-calorie diet high in fibre, potassium, calcium, and magnesium, with an emphasis on fruits, vegetables, and low-fat dairy foods and low in saturated and total fat, is recommended to help prevent and reduce the effects of hypertension (Joint National Committee [JNC], 2003).

Inadequate Exercise. Exercise increases the body's metabolic activity and oxygen demand. The rate and depth of respiration increase, enabling the person to inhale more oxygen and exhale excess carbon dioxide. A physical exercise program

has many benefits (see Chapter 35). People who exercise for one hour daily have a lower pulse rate and blood pressure, decreased cholesterol level, increased blood flow, and greater oxygen extraction by working muscles. Fully conditioned people can increase oxygen consumption by 10% to 20% because of increased cardiac output and increased efficiency of the myocardial muscle (JNC, 2003).

Smoking. Cigarette smoking is associated with a number of diseases, including heart disease, chronic obstructive lung disease, and lung cancer. Smoking is a risk factor for heart disease, stroke, cancer, and respiratory disease (Heart and Stroke Foundation of Canada, 2008). Inhaled nicotine causes vasoconstriction of peripheral and coronary blood vessels, increasing blood pressure and decreasing blood flow to peripheral vessels. Women who take birth control pills and smoke cigarettes are at increased risk for cardiovascular problems such as thrombophlebitis and pulmonary emboli.

Cigarette smoking is the major cause of lung cancer, accounting for 85% of all new cases of lung cancer in Canada (Health Canada, 2011). Regular exposure to second-hand smoke increases the chances of contracting lung disease by 25% and heart disease by 10% (Health Canada, 2007). Lung cancer is the leading cause of cancer death for both men and women (Canadian Cancer Society, 2011). It is estimated that 1 in 11 men and 1 in 15 women will develop lung cancer in their lifetime (Canadian Cancer Society, 2011). The 5-year survival rate (2004–2006) for females with lung cancer is 19% and in males 13% (Canadian Cancer Society, 2011). If lung cancer is detected when the disease is still localized, the survival rate is 49%. However, lung cancer is often diagnosed only when it has reached an advanced stage. If a substantial number of health care providers implement even minimal smoking cessation interventions, there will be a decrease in related tobacco diseases (Registered Nurses' Association of Ontario [RNAO], 2007, p. 13). RNAO (2007) has developed best practice guidelines and recommendations for nurses as they assist their patients with smoking cessation (see RNAO Best Practice Guideline *Integrating Smoking Cessation Into Daily Nursing Practice*).

Substance Abuse. Excessive use of alcohol and other drugs can impair tissue oxygenation in two ways. First, the person who chronically abuses substances often has a poor nutritional intake. With the resultant decrease in intake of iron-rich foods, hemoglobin production declines. Second, excessive use of alcohol and certain other drugs can depress the respiratory centre, reducing the rate and depth of respiration and the amount of inhaled oxygen. Substance abuse by either smoking or inhaling, such as crack cocaine or inhaling fumes from paint or glue cans, causes direct injury to lung tissue that can lead to permanent lung damage and impaired oxygenation.

Stress. A continuous state of stress or severe anxiety increases the body's metabolic rate and the oxygen demand. The body responds to anxiety and other stresses with an increased rate and depth of respiration. Most people can adapt, but some, particularly those with chronic illnesses or acute life-threatening illnesses such as a myocardial infarction, cannot tolerate the oxygen demands associated with anxiety (see Chapter 29).

Environmental Factors

The environment can also influence oxygenation. The incidence of pulmonary disease is higher in smoggy, urban areas than in rural areas. In addition, the patient's workplace may

increase the risk for pulmonary disease. Some occupational pollutants are asbestos, talcum powder, dust, and airborne fibres. Asbestosis is an occupational lung disease that develops after exposure to asbestos. The lung in asbestosis is characterized by diffuse interstitial fibrosis, creating a restrictive lung disease. It can also cause pleural mesotheliomas and pleural plaques. Patients at risk for developing asbestosis include those working with textiles, fireproofing, or milling, or in the production of paints, plastics, or some prefabricated construction. Patients exposed to asbestos who also smoke are at increased risk of developing lung cancer.

Critical Thinking

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking qualities, and intellectual and professional standards. Clinical judgements require you to anticipate the information necessary, analyze the data, and make decisions regarding the patient's care. During the assessment, consider all elements that build toward making an appropriate nursing diagnosis (Figure 38-6).

Figure 38-6 Critical thinking model for oxygenation assessment.

To understand the oxygen demands of a patient and the ability of the patient's body to meet those demands, you need to integrate knowledge from nursing and other disciplines, previous experiences, and information gathered from patients. Professional standards, such as those developed by the Heart and Stroke Foundation of Canada, the Canadian Lung Association, the Canadian Thoracic Society, and the Canadian Infectious Diseases Society, provide valuable guidelines for the care and management of patients with altered oxygenation.

Nursing Process

◆ Assessment

The nursing assessment of a patient's cardiopulmonary functioning includes an in-depth history of the patient's normal and present cardiopulmonary function, past impairments in circulatory or respiratory functioning, and measures that the patient uses to optimize oxygenation. The history should include a review of drug, food, and other allergies, such as pet dander, mould, and environmental triggers.

Physical examination of the patient's cardiopulmonary status reveals the extent of existing signs and symptoms. A review of laboratory and diagnostic test results provides valuable data on respiratory and ventilatory parameters.

Health History

The health history should focus on the patient's ability to meet oxygen needs. The health history for cardiac function includes pain and characteristics of pain, dyspnea, fatigue, peripheral circulation, cardiac risk factors, and the presence of past or concurrent cardiac conditions. The health history for respiratory function includes presence of a cough, shortness of breath, wheezing, pain, environmental exposures, frequency of respiratory tract infections, pulmonary risk factors, past respiratory problems, current medication use, and smoking history or second-hand smoke exposure.

Pain. Chest pain needs to be thoroughly evaluated with regard to location, duration, radiation, and frequency. Cardiac pain does not occur with respiratory variations and is most often on the left side of the chest and radiates to the left arm in men. Chest pain in women is much less definitive and may be a sensation of choking, breathlessness, or pain that radiates through to the back. Pericardial pain resulting from an inflammation of the pericardial sac is usually nonradiating and may occur with inspiration.

Pleuritic chest pain is peripheral and may radiate to the scapular regions. It is worsened by inspiratory manoeuvres, such as coughing, yawning, and sighing. Pleuritic pain is often caused from an inflammation or infection in the pleural space and is described as knifelike, lasting from a minute to hours and always in association with inspiration.

Musculoskeletal pain may be present following exercise, rib trauma, and prolonged coughing episodes. This pain is also aggravated by inspiratory movements and may easily be confused with pleuritic chest pain.

Fatigue. Fatigue is a subjective sensation in which the patient reports a loss of endurance. Fatigue in the patient with cardiopulmonary alterations is often an early sign of a worsening of the chronic underlying process. To provide an objective measure of fatigue, the patient may be asked to rate the fatigue on a scale of 0 to 10, with 10 being the worst level of fatigue and 0 representing no fatigue.

Smoking. It is important to determine patients' direct and secondary exposure to cigarette smoke. Ask the patient about any history of smoking; include the number of years smoked and the number of packages smoked per day. This is recorded as pack-year history. For example, if a patient smoked two packs a day for 20 years, the patient would have a 40 pack-year history (packages per day × years smoked).

It is also important to determine if the patient is exposed to second-hand smoke from family or co-workers. Exposure to second-hand smoke increases the patient's risk for chronic lung or cardiac diseases.

Dyspnea. Dyspnea is a clinical sign of hypoxia and manifests as breathlessness. It is the subjective sensation of difficult or uncomfortable breathing. Dyspnea is shortness of breath associated with exercise or excitement, but in some patients dyspnea may be present without any relation to activity or exercise. Dyspnea is associated with many conditions, such as pulmonary diseases, cardiovascular diseases, neuromuscular conditions, and anemia. Guidelines have been developed by the Registered Nurses' Association of Ontario (RNAO, 2005) to address nursing assessment and management of patients experiencing dyspnea associated with COPD (see the RNAO's Best Practice Guideline, *Nursing Care of Dypnea: The 6th Vital Sign in Individuals With Chronic Obstructive Pulmonary Disease [COPD]*). In addition, dyspnea may occur in the pregnant woman in the final months of pregnancy. Environmental factors, such as pollution, cold air, and smoking, may also cause or worsen dyspnea.

Dyspnea can be associated with clinical signs such as exaggerated respiratory effort, use of the accessory muscles of respiration, nasal flaring, and marked increases in the rate and depth of respirations (Jevon & Ewens, 2001). The use of a visual analogue scale (VAS) can help patients make an objective assessment of their dyspnea. The VAS is a 100-mm vertical line with end points of 0 and 10. Zero is equated with no dyspnea and 10 is equated with the worst breathlessness the patient has experienced. Studies have validated the use of the VAS to evaluate a patient's dyspnea in the clinical setting. Evaluate the effectiveness of nursing interventions by monitoring the patient's assessment of their dyspnea.

If the patient has a history of dyspnea, determine the circumstances under which it occurred, such as with exertion, stress, or respiratory tract infection. Determine whether the patient's perception of dyspnea affects the ability to lie flat. **Orthopnea** is an abnormal condition in which the person must use multiple pillows when lying down or must sit with the arms elevated and leaning forward to breathe. The number of pillows required for sleeping, such as two- or three-pillow orthopnea, usually quantifies the presence of orthopnea.

Cough. Cough is a sudden, audible expulsion of air from the lungs. The person breathes in, the glottis is partially closed, and the accessory muscles of expiration contract to expel the air forcibly. Coughing is a protective reflex to clear the trachea, bronchi, and lungs of irritants and secretions. The carina, the point of bifurcation of the right and left mainstem bronchus, is the most sensitive area for cough production. A cough is difficult to evaluate, and almost everyone has periods of coughing. Patients with a chronic cough tend to deny, underestimate, or minimize their coughing, often because they are so accustomed to it that they are unaware of how frequently it occurs.

Coughing is classified according to the time when the patient most frequently coughs. Patients with chronic sinusitis may cough only in the early morning or immediately after

rising from sleep. This clears the airway of mucus resulting from sinus drainage. Patients with chronic bronchitis generally produce sputum all day, although greater amounts are produced after rising from a semi-recumbent or flat position. This is a result of the dependent accumulation of sputum in the airways and is associated with reduced mobility (see Chapter 45). When a patient has a cough, determine its frequency and whether it is productive or nonproductive. A productive cough results in sputum production, material coughed up from the lungs that may be swallowed or expectorated. Sputum contains mucus, cellular debris, and microorganisms, and it may contain pus or blood. Collect data about the type and quantity of sputum. Instruct the patient to try to produce some sputum, being careful not to simply clear the throat to produce a sample of saliva. Then inspect it for colour, consistency, odour, and amount (Box 38-6).

If **hemoptysis** (bloody sputum) is reported, determine if it is associated with coughing and bleeding from the upper respiratory tract, from sinus drainage, or from the gastrointestinal tract (**hematemesis**). In addition, the hemoptysis should be described according to amount, colour, and duration and whether it is mixed with sputum. When the patient reports bloody or blood-tinged sputum, diagnostic tests, such as examination of sputum specimens, chest X-ray examinations, **bronchoscopy**, and other X-ray studies, should be performed.

Wheezing. Wheezing is characterized by a high-pitched musical sound caused by high-velocity movement of air through a narrowed airway. Wheezing may be associated with asthma, acute bronchitis, or pneumonia. Wheezing can occur on inspiration, expiration, or both. Determine if there are any precipitating factors, such as respiratory infection, allergens, exercise, or stress.

Environmental or Geographical Exposures. Environmental exposure to many inhaled substances is closely linked with respiratory disease. Investigate exposures in the patient's home and workplace. The most common environmental exposures in the home are cigarette smoke, carbon monoxide, and radon. In addition, determine whether a patient who is a nonsmoker is passively exposed to smoke.

Carbon monoxide poisoning can result from a blocked furnace flue or fireplace. The patient may have vague complaints of general malaise, flu-like symptoms, and excessive

sleepiness. Patients are particularly at risk in the late fall when they turn the heat on or begin to use the fireplace again. Radon gas, a radioactive substance that can damage lung tissue and cause lung cancer, enters homes through the ground. When homes are underventilated, this gas is not able to escape into the atmosphere and becomes trapped in the home.

Obtain an employment history to assess exposure to substances such as asbestos, coal, cotton fibres, fumes, or chemical inhalants. This is particularly important with middle-aged and older adults, who may have worked in places without regulations to protect workers from carcinogens such as asbestos.

Exposure to pathogens may occur during travel. Schistosomiasis can be acquired in Asia, Africa, the Caribbean, and South America. This is infection of a human with a species of fluke found in fresh water that has been contaminated by human feces. Coccidioidomycosis is a fungal disease caused by inhalation of *Coccidioides immitis*, a wind-borne spore carried on dust particles.

Respiratory Infections. A health history should contain information about the patient's frequency and duration of respiratory tract infections. Although everyone occasionally experiences a cold, for some people it can result in bronchitis or pneumonia. On average, patients will have four colds per year. Determine if the patient has had a pneumococcal or flu vaccine in the past and ask about any known exposure to tuberculosis (TB) and the results of the tuberculin skin test.

Determine the patient's risk for human immunodeficiency virus (HIV) infection. Patients with a history of intravenous (IV) drug use and multiple unprotected sexual partners are at risk of developing HIV infection. Patients may not display any symptoms of HIV infection until they present with *Pneumocystis carinii* (PCP) or *Mycoplasma pneumonia*. Presentation with PCP or *Mycoplasma pneumonia* indicates a significant depression of the patient's immune system and progression to acquired immune deficiency syndrome (AIDS).

Allergies. When obtaining a respiratory system history, inquire about airborne allergens. The patient's allergic response may be watery eyes, sneezing, runny nose, or respiratory symptoms, such as cough or wheezing. Ask the patient specific questions about the type of allergens, response to these allergens, and successful and unsuccessful relief measures. In addition, determine the impact that environmental air quality and second-hand smoke exposure has on the patient's allergy and symptoms.

Safe nursing practice also includes obtaining information about food, drug, or insect-sting allergies. These data are usually obtained on initial history and physical examination. However, always double-check this information with the patient, especially when obtaining information about respiratory allergens.

Health Risks. Investigate familial risk factors, such as a family history of lung cancer or cardiovascular disease. Documentation should include which blood relatives have had the disease and their present level of health or age at time of death. Other family risk factors include the presence of infectious diseases, particularly TB. It is important to determine who in the patient's household has been infected and the status of treatment.

Medications. The health history should also list medications the patient is using. These could include prescribed, over-the-counter, folk medicine, herbal medicines, alternative therapies, and illicit drugs and substances. Such medications may have adverse effects by themselves or through interactions

► **TABLE 38-3** Assessment Findings in the Aging Cardiopulmonary System

Function	Pathophysiological Change	Key Clinical Findings
Heart		
Muscle contraction	Thickening of the ventricular wall, increased collagen and decreased elastin in the heart muscle	Decreased cardiac output Diminished cardiac reserve
Blood flow	Heart valves become thicker and stiffer, more often in the mitral and aortic valves.	Systolic ejection murmur
Conduction system	The SA node becomes fibrotic from calcification; the number of pacemaker cells in the SA node decreases.	Increased PR, QRS, and Q-T intervals, decreased amplitude of the QRS complex
Arterial vessel compliance	Vessels become calcified, loss of arterial distensibility, decreased elastin in the vessel walls, more bends and twists (tortuous) in the vessels	Hypertension, with an increase in systolic blood pressure Fluctuation in blood pressure
Lungs		
Breathing mechanics	Decreased chest wall compliance, loss of elastic recoil Decreased respiratory muscle mass/strength	Prolonged exhalation phase Decreased vital capacity
Oxygenation	Increased ventilation-perfusion mismatch Decreased alveolar surface area Decreased carbon dioxide diffusion capacity	Decreased PaO ₂ (arterial oxygen tension) Decreased cardiac output Slightly increased PaCO ₂ (arterial carbon dioxide tension)
Breathing control/ breathing pattern	Decreased responsiveness of central and peripheral chemoreceptors to hypoxemia and hypercapnia	Increased respiratory rate Decreased tidal volume
Lung defence mechanisms	Decreased number of cilia Decreased IgA production and humoral and cellular immunity	Decreased airway clearance Diminished cough reflex
Sleep and breathing	Decreased respiratory drive Decreased tone of upper airway muscles	Increased risk of aspiration and infection Decreased PaO ₂ Snoring, obstructive sleep apnea

with other drugs. A person using a prescribed bronchodilator drug, for example, may decide that using an over-the-counter inhalant as well will be beneficial. Many of these contain ephedrine or ma huang, a natural chemical that acts like epinephrine. This product may react with the prescribed medication by potentiating or decreasing the effect of the prescribed medication. Patients taking warfarin (Coumadin) for blood thinning will prolong the prothrombin time (international normalized ratio [INR]) results if they are taking ginkgo biloba, garlic, or ginseng with the anticoagulant. The drug interaction could precipitate a life-threatening bleed.

safety alert During history taking, ask patients to list all of the over-the-counter and herbal supplements they are taking to ensure that medication interactions do not develop.

When patients are prescribed drugs for which toxic levels can be monitored by blood analyses, you need to review these laboratory values. Common drugs that can be monitored are theophylline (theophylline levels), digitalis preparations (digitalis levels), anticoagulants such as warfarin (Coumadin; INR level), and phenobarbital (phenobarbital levels). Toxic effects of these medications can impair cardiopulmonary functioning.

It is important to determine whether a patient uses illicit drugs. These drugs, particularly parenterally administered narcotics, which are often diluted with talcum powder, can cause pulmonary disorders resulting from the irritant effect of the powder on lung tissues.

As with all medication, assess the patient's knowledge and ability to self-administer medications correctly (see Chapter 33). Of particular importance is the assessment of the patient's understanding of potential side effects of the medications.

Patients should be able to recognize adverse reactions and be aware of the dangers in combining prescribed medications with over-the-counter drugs.

Physical Examination

The physical examination performed to assess the patient's level of tissue oxygenation includes evaluation of the cardiopulmonary system (see Chapter 31). Special consideration should be given when assessing the older patient because changes in the cardiopulmonary system occur with the aging process (Table 38-3). These changes may result in changes in the patient's activity tolerance, level of fatigue, or transient changes in vital signs and may not be associated with a specific cardiopulmonary disease.

Inspection. Using inspection techniques, perform a head-to-toe observation of the patient for skin and mucous membrane colour, general appearance, level of consciousness, adequacy of systemic circulation, breathing patterns, and chest wall movement (Table 38-4). Any abnormalities should be investigated during palpation, percussion, and auscultation.

Inspection includes observations of the nails for clubbing. Clubbed nails, obliteration of the normal angle between the base of the nail and the skin, are seen in patients with prolonged oxygen deficiency, endocarditis, and congenital heart defects.

Observe the chest wall movement for retraction, sinking in of soft tissues of the chest between the intercostal spaces. Also observe for paradoxical breathing, asynchronous breathing, and the patient's breathing pattern (Table 38-5). In paradoxical breathing, the chest wall contracts during inspiration and expands during exhalation. Infants can experience sternal and substernal chest wall retractions with only a slight inspiratory effort because of the pliability of the chest wall. Note the anteroposterior diameter of the chest wall. Conditions such as

► **TABLE 38-4** **Inspection of Cardiopulmonary Status**

Abnormality	Cause
Eyes	
Xanthelasma (yellow lipid lesions on eyelids)	Hyperlipidemia
Corneal arcus (whitish opaque ring around junction of cornea and sclera)	Hyperlipidemia in young to middle-aged adults, normal finding in older adults with arcus senilis
Pale conjunctivae	Anemia
Cyanotic conjunctivae	Hypoxemia
Petechiae on conjunctivae	Fat embolus or bacterial endocarditis
Mouth and Lips	
Cyanotic mucous membranes	Decreased oxygenation (hypoxia)
Pursed-lip breathing	Associated with chronic lung disease
Neck Veins	
Distension	Associated with right-sided heart failure
Nose	
Flaring nares	Air hunger, dyspnea
Chest	
Retractions	Increased work of breathing, dyspnea
Asymmetry	Chest wall injury
Skin	
Peripheral cyanosis	Vasoconstriction and diminished blood flow
Central cyanosis	Hypoxemia
Decreased skin turgor	Dehydration (normal finding in older adults as a result of decreased skin elasticity)
Dependent edema	Associated with right-sided heart failure
Periorbital edema	Associated with kidney disease
Fingertips and Nail Beds	
Cyanosis	Decreased cardiac output or hypoxia
Splinter hemorrhages	Bacterial endocarditis
Clubbing	Chronic hypoxemia

Source: Potter, P. A., & Weillitz, P. B. (2007). *Health assessment: Pocket guide series* (6th ed.). St. Louis, MO: Mosby.

emphysema, advancing age, and COPD can cause the chest to assume a rounded shape.

Palpation. Palpation of the chest provides assessment data in several areas. It documents the type and amount of thoracic excursion, elicits any areas of tenderness, and can identify tactile fremitus, thrills, heaves, and the cardiac point of maximal impulse (PMI). Palpation also aids in detecting abnormal masses or lumps in the axilla and breast tissue. Palpation of the extremities provides data about the peripheral circulation, the presence and quality of peripheral pulses, skin temperature, colour, and capillary refill (see Chapter 31).

Palpation should also include the feet and legs to assess the presence or absence of peripheral edema. Patients with alterations in their cardiac function, such as those with congestive

heart failure or hypertension, often have pedal or lower extremity edema. Edema is graded from 1+ to 4+, depending on the depth of visible indentation after firm application of a finger (see Chapter 31).

Palpation of the pulses in the neck and extremities is performed to assess arterial blood flow (see Chapter 31 and Box 38-7). A scale of 0 (absent pulse) to 3+ (full, bounding pulse) is used to describe what is palpated. The normal pulse is graded at 2+, and a weak, thready pulse is graded as 1+.

Percussion. Percussion is used to detect the presence of abnormal fluid or air in the lungs. It also aids in determining diaphragmatic excursion (see Chapter 31).

Auscultation. Auscultation helps in identifying normal and abnormal heart and lung sounds (see Chapter 31). Auscultation of the cardiovascular system should include assessment for normal S₁ and S₂ sounds, the presence of abnormal S₃ and S₄ sounds (gallops), and murmurs or rubs. Auscultation is also used to identify a bruit over the carotid arteries, abdominal aorta, and femoral arteries.

Auscultation of lung sounds involves listening for movement of air throughout all lung fields: anterior, posterior, and lateral. Adventitious breath sounds occur with collapse of a lung segment, fluid in a lung segment, or narrowing or obstruction of an airway. Auscultation also evaluates the patient's response to interventions for improving the respiratory status.

Diagnostic Tests

There are a variety of diagnostic tests to monitor cardiopulmonary functioning. Some of these tests can be obtained through screening, simple blood specimens, X-ray films, or other non-invasive means. One such screening mechanism is TB skin testing (Box 38-8). This is a simple test that is usually required annually for health care workers to monitor possible TB exposure. In contrast, invasive diagnostic tests, such as a thoracentesis, can be quite painful, depending on the patient's tolerance for pain.

Tables 38-6 and 38-7 and Box 38-9 summarize diagnostic testing used in the assessment and evaluation of patients with cardiopulmonary alterations. Explain the procedure and tell the patient what to expect, to reduce the patient's anxiety. The patient must understand the importance of following instructions, such as holding the breath as requested and not coughing during the procedure. After any procedure, monitor the patient for signs of changes in cardiopulmonary functioning, sudden shortness of breath, pain, oxygen desaturation, and anxiety. Promote the patient's comfort and encourage the patient to rest after the test, because many patients find these tests to be tiring.

Patient Expectations

Ask patients what they expect from the encounter and what their priority is for management of their health. In identifying expectations, you involve patients in the decision-making process and allow them to participate in their care and know what will happen to them. For example, if you plan a smoking-cessation or weight-reduction program for a patient who is not ready for the change, both you and the patient will become frustrated. Establish short-term, realistic goals that build to a larger goal. For example, reducing the fat in the patient's diet might start out with replacing food such as whole milk with 2% milk and gradually introducing skim milk. A sudden change from whole to skim milk will most likely fail, because the change is too much. A plan for adding exercise to the

► **TABLE 38-5** Assessment of Breathing Pattern**Pattern and Rate (Breaths/Minute)**

Eupnea (12–20)

Tachypnea (>20)

Bradypnea (<12)

Apnea (absence of respiration >15 seconds)

Kussmaul's respirations (usually >35, may be slow or normal)

**Clinical Significance**

Normal rate in the adult

Can result from anxiety or response to pain or fever, respiratory failure, shortness of breath, or a respiratory infection. May lead to respiratory alkalosis, paresthesia, tetany, and confusion

Results from sleep, respiratory depression, drug overdose, or central nervous system lesion

May be intermittent, such as in sleep apnea, or prolonged, as in a respiratory arrest

Tachypnea pattern associated with metabolic imbalance such as diabetic ketoacidosis, metabolic acidosis, or renal failure

BOX 38-7 NURSING STORY

My First Maternal-Child Clinical Experience

It was one of my first clinical experiences as a student nurse. I was placed on a maternity unit with seven other students. Because I was so nervous, I asked another student colleague to accompany me while I recorded vital signs on a newborn baby. I entered the room, introduced myself to the baby's mother, and grasped for the baby's wrist to check the heart rate. I had a hard time finding the pulse; it felt like hours before I finally felt what I hoped was the pulse. As I began counting each heartbeat, the responsible registered nurse entered the room and said, "Oh, are you trying to get the heart rate?" I was relieved that help had arrived. She advised me, "You need to use your stethoscope to listen to the apical pulse." I was so embarrassed, and even more nervous. I immediately put the stethoscope on the baby's chest. Confused, I told the student standing next to me, "I still can't hear anything." She smiled and pointed to the earpieces, which were sitting around my neck instead of in my ears.

patient's lifestyle could start with a commitment to exercise once a week for 20 minutes, or the patient could commit to a weight-reduction plan of 2 kg per month.

Remember that your goals and expectations may not always coincide with those of your patient. By addressing the patient's concerns and expectations, you will establish a relationship that can address other health care goals and expected outcomes. Knowing the mindset of patients and respecting their wishes will go a long way toward helping patients make significant lifestyle changes to benefit their health.

► BOX 38-8 Tuberculosis Skin Testing

- Skin testing is used to determine past exposure to *Mycobacterium tuberculosis*.
- Tuberculosis skin testing (TST) is performed by administering an intradermal injection of 0.1 mL of tuberculin-purified protein derivative on the inner surface of the forearm. The injection produces a pale elevation of the skin (a wheal) 6–10 mm in diameter. Afterward, the injection site may be circled, and the patient is instructed not to wash off the circle.
- Tuberculin skin tests are read 48–72 hours after injection. If the site is not read within 72 hours, the patient must undergo another skin test.
- Positive results are indicated by a palpable, elevated, hardened, reddened area around the injection site, caused by edema and inflammation from the antigen–antibody reaction. The site is measured in millimetres. A positive test result occurs when the site is ≥ 10 mm.
- Reddened flat areas are *not* positive reactions and are not measured.
- TST in older adults is less reliable (see Box 38-4).

❖ **Nursing Diagnosis**

Patients with an altered level of oxygenation can have nursing diagnoses that are primarily from a cardiovascular or pulmonary origin. Each nursing diagnosis is based on specific defining characteristics and the related etiology (Box 38-10). Use the information gathered in the nursing assessment to identify and

► **TABLE 38-6** Cardiopulmonary Diagnostic Blood Studies

Test and Normal Values	Interpretation
Complete Blood Count (CBC) Normal values for a CBC vary with age and gender.	A CBC determines the number and type of red and white blood cells per cubic millimetre of blood.
Cardiac Blood Studies CK (Creatinine Kinase) MB Levels rise 3–6 hours after infarction occurs. Peaks in 18 hours and then returns to normal within two days. Two cardiac specific troponins released after a myocardial infarction: Troponin T (cTnt) and Troponin I (cTnl). Cardiac troponin I <0.03 ng/mL Cardiac troponin T <0.2 ng/mL B-Type Natriuretic Peptide (BNP) BNP < 100 ng/L	Cardiac enzymes are used to diagnose acute myocardial infarcts. CK-MB is specific to the myocardial cell and may quantify myocardial damage and timing of the onset of the infarction. Cardiac troponins become elevated as early as three hours after myocardial injury. Often remains elevated for 7–10 days. Often remains elevated for up to 10–14 days. BNP is a marker for heart failure and assists with identifying pulmonary or cardiac causes for shortness of breath. The more elevated the levels, the more severe the heart failure.
Serum Electrolytes Potassium (K ⁺) 3.5–5 mmol/L	Patients on diuretic therapy are at risk for hypokalemia (low potassium). Patients receiving angiotensin-converting enzyme inhibitors are at risk for hyperkalemia (elevated potassium).
Cholesterol Cholesterol <5.20 mmol/L Low-density lipoprotein (LDL) cholesterol (bad cholesterol) <3.4 mmol/L High-density lipoprotein (HDL) cholesterol (good cholesterol) Male: >0.75 mmol/L Female: >0.91 mmol/L Triglycerides Male: 0.45–1.81 mmol/L Female: 0.40–1.52 mmol/L	Contributing factors include sedentary lifestyle, intake of saturated fatty acids, and familial hypercholesterolemia. High LDL cholesterol (hypercholesterolemia) is caused by excessive intake of saturated fatty acids, dietary cholesterol intake, and obesity. Familial hypercholesterolemia and hyperlipidemia are also contributing factors, as are hypothyroidism, nephrotic syndrome, and diabetes mellitus. Low HDL cholesterol is caused by cigarette smoking, obesity, lack of regular exercise, β -adrenergic blocking agents, genetic disorders of HDL metabolism, hypertriglyceridemia, and type 2 diabetes. Obesity, excessive alcohol intake, diabetes mellitus, β -adrenergic blocking agents, and genetic predisposition cause hypertriglyceridemia.

Data from Pagana, K. D., & Pagana, T. J. (2010). *Mosby's manual of diagnostic and laboratory tests* (4th ed.). St Louis, MO: Mosby.

► **TABLE 38-7** Cardiac Function Diagnostic Tests

Test	Significance
12-Lead electrocardiogram (ECG)	Graphic recording of the electrical activity of the heart, used to detect abnormal electrical activity and the electrical position of the heart. The ECG includes 12 leads: I, II, III, AVR, AVL, AVF, and V1–6. It provides a 360-degree view of the heart.
Holter monitor	Portable ECG worn by the patient. The test produces a continuous ECG tracing over a period of time. Patients keep a diary of activity, noting when they experience rapid heartbeats or dizziness. Evaluation of the ECG recording along with the diary provides information about the heart's electrical activity during activities of daily living.
ECG exercise stress test	ECG is monitored while the patient walks on a treadmill at a specified speed and duration of time. Used to evaluate the cardiac response to physical stress. The test is not a valuable tool for evaluation of cardiac response in women because of increased false-positive findings among women.
Thallium stress test	An ECG stress test with the addition of thallium-201-injected IV. The test determines coronary blood flow changes with increased activity.
Electrophysiological study (EPS)	Invasive measure of intracardiac electrical pathways. Provides more specific information about difficult-to-treat dysrhythmias. EPS assesses the adequacy of antidysrhythmic medication.
Echocardiography	Noninvasive measure of heart structure and heart wall motion. Graphically demonstrates overall cardiac performance.
Scintigraphy	Radionuclide angiography. Used to evaluate cardiac structure, myocardial perfusion, and contractility.
Cardiac catheterization and angiography	Used to visualize cardiac chambers, valves, the great vessels, and coronary arteries. Pressures and volumes within the four chambers of the heart can also be measured.

► BOX 38-9 Common Respiratory Tests and Methods

Oxygenation Tests

- **Pulse oximetry:** A **pulse oximeter** is a device used to measure pulse rate and oxygen concentration in arterial blood (SaO_2). A sensor is attached to the patient's finger, toe, nose, earlobe, or forehead. Accuracy is directly related to the perfusion of the probe area, a systolic blood pressure >90 mm Hg, and the hemoglobin level. Decreased levels correlate well with arterial oxygen levels and are used to trend oxygenation over time. Normal SaO_2 values are 98%–100%. An SaO_2 below 70% is life-threatening.
- **Arterial blood gas:** A radial or femoral artery is punctured to obtain arterial blood. Tests measure the oxygen concentration in the blood, the hydrogen ion concentration (pH), partial pressure of carbon dioxide (PaCO_2), and the partial pressure of oxygen (PaO_2). Normal values are as follows:
 - pH 7.35–7.45
 - PaCO_2 35–45 mm Hg
 - PaO_2 80–100 mm Hg
 - SaO_2 95%–100%

Pulmonary Function Tests

Pulmonary function tests measure lung volume (the amount of air moving into and out of the lungs) and capacity (how much air the lungs can hold). Respiratory therapists usually conduct these tests. The patient takes as deep a breath as possible and forcefully exhales into a mouthpiece attached to a machine. Pulmonary readings are recorded and compared with previous readings and with average normal values, which vary depending on the patient's age, gender, weight, height, and race. These tests are used to diagnose and monitor pulmonary disease and conditions (e.g., asthma, emphysema). They are also used to evaluate postoperative lung conditions.

Imaging

- **Chest X-ray examination:** Usually posteroanterior and lateral films are taken to adequately visualize all of the lung fields. A radiograph of the thorax is used to observe the lung fields for fluid, infiltrates (e.g., pneumonia), masses (e.g., lung cancer), fractures, pneumothorax, and other abnormal processes.
- **Computed tomography (CT) scan:** A CT scan provides visualization of fine detail of the lungs and other structures in the thorax. It is often used as part of the assessment of patients with pneumonia, lung masses, and suspected pulmonary emboli.
- **Ventilation/perfusion (nuclear medicine) lung scan:** This scan is used to detect pulmonary emboli. The results from two separate

scans are compared: the perfusion scan uses an injected radioactive tracer to measure pulmonary blood flow, and the ventilation scan shows the pulmonary distribution of a different inhaled tracer. Mismatches (areas of ventilation without corresponding perfusion or blood flow) indicate pulmonary emboli.

Methods of Obtaining Respiratory Specimens for Analysis

Specimens are cultured so they can be used to detect the presence of blood, microbes, and abnormal cells. A variety of methods are used to obtain respiratory specimens.

- **Sputum tests:** Sputum is mucus from the respiratory system that is expectorated through the mouth. Sputum specimens are obtained when the patient coughs up sputum from the bronchi and trachea; specimens are easier to obtain in the morning when the secretions are coughed up upon awakening. Sputum tests include (a) *sputum culture and sensitivity (C and S)* test, used to identify a specific microorganism growing in the sputum and to identify drug resistance and sensitivities; (b) *sputum for acid-fast bacillus (AFB)*, a test used to screen for the presence of AFB for detection of TB by early-morning specimens on three consecutive days; and (c) *sputum for cytology*, used to identify abnormal lung cancer and differentiates the type of cancer cells (small cell, oat cell, large cell).
- **Tracheal aspiration via endotracheal tube in intubated patients:** Secretions are collected by passing a flexible suction catheter through the endotracheal tube.
- **Bronchoscopy:** A narrow, flexible, fiberoptic scope is passed into the trachea and bronchi to enable visual examination of the tracheobronchial tree. The procedure is performed to obtain fluid, sputum, or biopsy samples, and to remove mucous plugs or foreign bodies.
- **Thoracentesis:** This involves surgical perforation of the chest wall and pleural space with a needle to aspirate fluid for diagnostic or therapeutic purposes or to remove a specimen for biopsy. The procedure is performed using aseptic technique and local anaesthetic. The patient usually sits upright with the anterior thorax supported by pillows or an overbed table.
- **Nasopharyngeal aspirate or swab:** This swab is used to detect respiratory viruses. Aspirates are the best specimens from young children, whereas swabs can be used for obtaining samples from older children and adults.

cluster the defining characteristics. The clustered defining characteristics support the nursing diagnosis.

Nursing diagnoses appropriate for the patient with alterations in oxygenation include, but are not limited to, the following:

- Activity intolerance
- Risk for activity intolerance
- Ineffective airway clearance
- Anxiety
- Ineffective breathing pattern
- Decreased cardiac output
- Impaired comfort
- Impaired verbal communication
- Ineffective individual coping
- Fatigue
- Fear

- Risk for imbalanced fluid volume
- Impaired gas exchange
- Ineffective health maintenance
- Risk for infection
- Deficient (specify) knowledge
- Risk for impaired skin integrity
- Disturbed sleep pattern
- Ineffective tissue perfusion
- Impaired spontaneous ventilation

❖ Planning

During planning, use critical thinking skills to synthesize information from multiple sources (Figure 38-7). Critical thinking ensures that your plan of care integrates individualized patient needs. Professional standards are especially important

BOX 38-10 NURSING DIAGNOSTIC PROCESS

Assessment Activities	Defining Characteristics	Nursing Diagnosis
Ask patient or family about patient's mood, attentiveness, memory, and activity level.	Confusion Decreased activity Fatigue Irritability Restlessness Sleepiness	<i>Impaired gas exchange related to decreased lung expansion</i>
Observe patient's respirations.	Dyspnea Impaired gas exchange related to collapsed alveoli Nasal flaring Tachypnea Use of accessory muscles	
Inspect skin and mucous membranes.	Diaphoresis Pallor Moist skin	
Auscultate chest.	Decreased respiratory excursion Abnormal, distant lung sounds	

to consider when developing a care plan. These standards often establish scientifically proven guidelines for selecting effective nursing interventions.

Goals and Outcomes

Develop an individualized care plan for each nursing diagnosis (Box 38-11). In collaboration with your patient, set realistic expectations for care. Goals should be individualized and realistic with measurable outcomes.

Patients with impaired oxygenation require a nursing care plan directed toward meeting the actual or potential oxygenation needs of the patient. Individual outcomes are derived from patient-centred needs. For example, the goal of maintaining a patent airway can be evaluated by specific outcomes for the patient. These might include the following expected outcomes:

- Patient's lungs are clear to auscultation.
- Patient achieves maintenance and promotion of bilateral lung expansion.
- Patient coughs productively.
- Tissue oxygenation (SaO_2) is maintained or improved.

Often a patient with cardiopulmonary disease has multiple nursing diagnoses (Figure 38-8). In this case, identify when goals or outcomes apply to more than one diagnosis. The presence of multiple diagnoses also makes priority setting a critical activity.

Setting Priorities

The patient's level of health, age, lifestyle, and environmental risks affect the level of tissue oxygenation. Patients with severe impairments in oxygenation frequently require nursing interventions in multiple areas. Consider what the most important goal is during the limited amount of time the patient is seen

Figure 38-7 Critical thinking model for oxygenation planning.

in the hospital or primary care setting. For example, in an acute care setting, maintaining a patent airway has a higher priority than improving the patient's exercise tolerance. The need for a patent airway is an immediate need. In a second example, when caring for a patient who has an abdominal incision, pain control may have a greater priority than coughing and deep breathing. Again, in this situation, controlling the patient's pain ultimately will facilitate coughing and deep breathing.

However, in a community-based or primary setting, the priority may focus on smoking cessation, exercise, diet modifications, or a combination of these activities. Both you and the patient need to be focused on the same goal and expected outcomes to be successful. In addition to being individualized, each goal should be realistic and attainable for the patient.

Collaborative Care

The time spent with the patient in any setting is limited. Therefore, collaborate with family members, colleagues, and other specialists to accomplish the goals and outcomes that have been determined. Some patients may need to improve their exercise and activity tolerance; for some patients, their continuity of care may involve enrolling in a community-based cardiopulmonary rehabilitation program. Another patient may

► BOX 38-11 NURSING CARE PLAN

Ineffective Airway Clearance/Retained Secretions

Assessment

Mr. Edwards, an older adult with a history of COPD, comes to the primary care office with complaints of continued coughing. He continues to smoke two to three cigarettes a day, an improvement from his previous 10 to 15 per day.

Assessment Activities

Ask Mr. Edwards how long he has had this cough.

Ask Mr. Edwards what is different about this cough.

Observe Mr. Edwards's skin and mucous membranes.

Auscultate lung fields.

Ask Mr. Edwards how many glasses of water he drinks daily.

Ask Mr. Edwards to produce a sputum sample.

Findings and Defining Characteristics

He replies, "I have a morning cough every day, but this cough is different. It started about a week ago."

He replies, "My ribs are getting sore. I can't cough up anything, my mouth is dry, and I have become more fatigued over the past week."

His skin and mucous membranes are dry.

Abnormal lung sounds in the upper lobes. The lower lobes are clear.

Over the last week he has drunk two to three glasses a day.

He is unable to produce a sputum sample for evaluation.

Nursing Diagnosis: Ineffective airway clearance related to retained secretions and reduced fluid intake.

Planning

Goals (Nursing Outcomes Classification)*

Patient will be able to effectively clear secretions.

Patient will increase oral hydration to 1000 mL of water every 24 hours.

Expected Outcomes

Respiratory Status: Airway Patency

Lung sounds will be normal in 48 hours.

Sputum will be thin, white, and watery.

Respiratory rate will be within 20–24 breaths/minute in 48 hours.

Patient will be able to clear airway by coughing.

Oral mucous membranes will be pink and moist.

Patient will verbalize that his mouth is not dry.

Patient will notice an increase in ease of sputum production.

Patient will report that his sputum is thin, white, and watery.

*Outcome classification labels from Moorhead, S., Johnson, M., Maas, M. L., & Swanson, E. (Eds.). (2008). *Nursing outcomes classification (NOC)* (4th ed.). St Louis, MO: Mosby.

Interventions (Nursing Interventions Classification)[†]

Airway Management

Increase fluids to 1000 mL in 24 hours if not contraindicated by cardiovascular disease (Lewis et al., 2000).

Have patient deep-breathe and cough every two hours four to five times (Lewis et al., 2000).

Teach patient effective cough techniques.

Consider chest physiotherapy (CPT) if there is evidence of infiltrates on chest X-ray film.

Rationale

Fluids help to liquefy secretions and promote ease of removal (Snow et al., 2001). Fluids will relieve oral mucosa and skin dryness.

Retained secretions predispose patient to atelectasis and pneumonia (Day et al., 2002).

Coughing techniques will help to clear the airway effectively and decrease fatigue from ineffective coughing (Snow et al., 2001).

Standards for CPT include sputum production >30 mL/day or infiltrates on chest X-ray film.

[†]Intervention classification labels from Bulechek, G. M., Butcher, H. K., & Dochterman, J. M. (Eds.). (2008). *Nursing interventions classification (NIC)* (5th ed.). St Louis, MO: Mosby.

Evaluation

Nursing Actions

Ask Mr. Edwards if he can deep-breathe and cough.

Assess the chest for adventitious lung sounds.

Patient Response and Findings

Mr. Edwards reports, "It is easier to cough up my secretions now."

Mr. Edwards reports that he has not heard any wheezing or rattling in his chest.

Achievement of Outcome

Patient is able to clear airway by coughing.

Lungs clear to auscultation in all fields.

BOX 38-11 NURSING CARE PLAN—cont'd

Nursing Actions	Patient Response and Findings	Achievement of Outcome
Assess respiratory rate.	No use of accessory muscles of respiration. Normal breathing pattern and respiratory rate.	Respiratory rate is between 20 and 24 breaths/minute.
Assess patient's level of hydration.	Mucous membranes are moist. Mr. Edwards reports, "My mouth isn't so dry anymore."	Oral mucous membranes are pink and moist.
Observe appearance of sputum.	Sputum is thin, white, and watery.	Sputum is thin, white, and watery.

have the same health care need but is unable to leave the home, and home physiotherapy is needed.

Collaboration with physiotherapists, nutritionists, and community-based nurses may be valuable for a patient with congestive heart failure or chronic lung conditions and is an essential component of primary health care. These professionals work with the patient and the community to optimize resources to assist the patient in attaining the highest level of wellness. In addition, professionals can help to identify community resources and support systems for both the patient and family in preventing and managing symptoms related to cardiopulmonary diseases.

❖ Implementation

Nursing interventions for promoting and maintaining adequate oxygenation include independent nursing actions such

as health-promotion and disease-prevention behaviours, positioning, and coughing techniques. Interdependent or dependent interventions include oxygen therapy, lung inflation techniques, hydration, medication administration, and chest physiotherapy (CPT).

Health Promotion

Maintaining the patient's optimal level of health is important in reducing the number and severity of respiratory symptoms. Prevention of respiratory infections is foremost in maintaining optimal health. Providing cardiopulmonary-related health information (Box 38-12 and Box 38-13) is an important nursing responsibility and part of a primary health care model.

Vaccinations. Annual influenza vaccines are recommended for children 6 to 23 months of age, older patients, and patients with chronic illnesses. This includes patients older than 65 years of age; patients of any age with chronic disease

* BOX 38-12 PATIENT TEACHING

Cardiovascular Disease

Objectives

- Patient will be able to describe the risk factors associated with cardiovascular disease.
- Patient will be able to demonstrate health promotion behaviours.

Teaching Strategies

- Explain to the patient about modifying risk factors, such as quitting smoking, reducing alcohol intake, and modifying high-fat and high-carbohydrate diets.
- Inform the patient about other risk factors for cardiovascular disease, such as diabetes, obesity, physical inactivity, stress, and oral contraceptives.
- Discuss with the patient the importance of regular blood pressure and blood cholesterol monitoring (total cholesterol, high-density lipoprotein, low-density lipoprotein, and triglyceride levels).
- Educate the patient about low-fat, low-salt, and calorie-appropriate diets. Provide sample menus.
- Educate the patient about the benefits of exercising for 30–60 minutes a day to help reduce weight and lower blood pressure. Help the patient develop an exercise program.

Evaluation

- Ask the patient to describe the modifiable and nonmodifiable risk factors for cardiovascular disease.
- Ask the patient to verbalize strategies for balanced nutrition.
- Obtain patient's weight and blood pressure.
- Monitor the patient's serum cholesterol (total, high- and low-density lipids) and triglyceride levels.

of the heart, lung, or kidneys; patients with diabetes; and patients with immunosuppression or severe forms of anemia. The vaccine is also recommended for people in close or frequent contact with anyone in the high-risk groups. In Canada, flu season occurs from November to April, and it is estimated that 10% to 25% of Canadians may get the flu each year. Although most individuals recover completely, an estimated 4000 to 8000 Canadians, mostly older adults, die every year from pneumonia related to the flu. Many others may die from other serious complications of the flu. After the vaccination, antibodies develop against the strains of the virus. When exposed to the influenza virus, the antibodies assist with preventing infection or reduce the severity of illness (Health Canada, 2009).

The value of vaccination of immunocompromised patients is not completely understood. HIV-positive patients may receive the flu vaccine; however, they may require a second vaccine to gain protection. People who should not be vaccinated include those with a known hypersensitivity to eggs or other components of the vaccine and adults with an acute febrile illness. The vaccines are formulated annually on the basis of worldwide surveillance data.

Pneumococcal vaccine is recommended for patients at increased risk of developing pneumonia, those with chronic illnesses or immunosuppression (such as HIV/AIDS), those living in special environments such as long-term care facilities, and patients over the age of 65 years (Centres for Disease Control and Prevention [CDC], 2010).

* BOX 38-13 RESEARCH HIGHLIGHT

Ethnic and Gender Differences in Patient Education About Heart Disease Risk and Prevention

Research Focus

Immigrants have lower rates of heart disease than the Canadian-born population after adjustment for differences in age, education, and income (Grunau et al., 2009, p. 181). The purpose of the study conducted by Grunau et al. (2009) was to understand whether gender and ethnic differences affect patient education about heart disease risk and prevention by health care providers. This study was part of a larger study that considered the relationship between sociodemographic, clinical, cognitive, psychological, social factors, and delay in treatment seeking for cardiac symptoms.

Research Abstract

A telephone survey was completed by a random sample of 976 men and women living in Metro Vancouver, British Columbia. The participants were categorized by their immigration status—those born in Canada and those that were not. The immigrant group was further divided based on two aspects: ethnicity—identity and language. The age of participants ranged from 40 to 89 years, with a mean of 55.5 years. The questionnaire was administered in four languages (English, Punjabi, Mandarin, and Cantonese) and assessed perceived communication with health care providers about heart disease risk and management education. Significant gender and ethnic differences were identified in health care providers' communication. Women were less likely than men to have had discussions regarding the management and their risk of heart disease with health care providers. In addition, Canadian-Chinese participants were less likely than other ethnic groups to receive information from their health care providers about heart disease.

Evidence-Informed Practice

- Emphasize heart disease education and its risk factors for women and postmenopausal women.
- Comprehend the seriousness of heart disease in women in order for women to understand the importance of primary and secondary prevention.
- The Canadian-Chinese population is not receiving patient education similar to that received by other communities; thus, it is important to understand the barriers faced by ethnic groups to develop solutions.

Reference: Grunau, G. L., Ratner, P. A., Galdas, P. M., & Hossain, S. (2009). Ethnic and gender differences in patient education about heart disease risk and prevention. *Patient Education and Counseling*, 76, 181–188. doi:10.1016/j.pec.2008.12.026.

Both the influenza vaccine and pneumococcal vaccine can be administered to pregnant women after the first trimester. However, in all cases, it is important to consult the patient's obstetrician before administering either vaccine.

Healthy Lifestyle Behaviour. Identification and elimination of risk factors for cardiopulmonary disease is an important part of primary health care. Encourage patients to eat a healthy, low-fat, high-fibre diet; monitor their cholesterol, triglyceride, high-density lipoprotein (HDL), and low-density lipoprotein (LDL) levels; reduce stress; exercise; and maintain a body weight in proportion to their height.

Elimination of cigarettes and other tobacco products, reduction of pollutants, monitoring of air quality, and adequate

hydration are additional healthy behaviours. Patients should be encouraged to examine their habits and make changes to achieve their goals.

Exercise is a key factor in promoting and maintaining a healthy heart and lungs. Patients should be encouraged to exercise 3 to 4 times a week for 20 to 30 minutes. Aerobic exercise is necessary to improve lung function, strengthen muscles, and achieve the desired outcome. Walking is one of the most efficient ways to achieve a good aerobic workout. Many shopping malls have programs that allow people to enter the mall before the shops open and use the enclosed area for walking. Some even have measured the distances to help people plan their activity and measure their progress. Patients should be taught how to take their pulse and pace themselves. It is better to walk 15 minutes every day than to walk to exhaustion to achieve a goal. Patients should plan a time interval and walk for the designated time. Gradually, they will notice that the distance increases as their endurance and fitness improve.

Patients with cardiopulmonary alterations need to minimize their risk for infection, especially during the winter months. Teach patients to avoid large, crowded places; to keep their mouth and nose covered; and to be sure to dress warmly, including a scarf, hat, and gloves. This is especially important during the peak of the influenza season.

Patients with known cardiac disease and those with multiple risk factors should be cautioned to avoid exertion in cold weather. Shovelling snow is especially risky and has been known to precipitate a cardiac event in many patients. Other activities such as hanging holiday lights and decorations in the extreme cold can precipitate chest pain and bronchospasm. Advise patients to avoid alcohol, because it blunts the respiratory drive when used in excess and may contribute to exposure to the cold by making the patient feel warm when the patient is really not protected.

Patients should also be taught to plan for the hot summer months. Activities should be limited to early in the day or late in the evening, when temperatures are lower. Patients should take care to maintain adequate hydration and sodium intake; this is especially true for those patients taking diuretics. Caffeinated and alcoholic beverages should be limited or avoided completely, because they act as diuretics and can contribute to dehydration.

Environmental Pollutants. Avoiding exposure to second-hand smoke is essential to maintaining optimal cardiopulmonary function. Most businesses and restaurants now ban smoking or have separate areas designated as smoking areas. If patients are exposed to second-hand smoke in their home environments, counselling and support may be necessary to assist the smoker in successful smoking cessation or alterations in behaviour patterns, such as smoking outside.

Exposure to chemicals and pollutants in the work environment must also be considered. Patients such as farmers, painters, carpenters, and others benefit from the use of particulate filter masks to reduce inhalation of particles.

Acute Care

Patients with acute pulmonary illnesses require nursing interventions directed toward halting the pathological process (e.g., respiratory tract infection), shortening the duration and severity of the illness (e.g., hospitalization with pneumonia), and preventing complications from the illness or treatments (e.g., nosocomial infection resulting from invasive procedures).

Dyspnea Management. Dyspnea is difficult to quantify and to treat. Treatment modalities need to be individualized for each patient, and more than one therapy is usually implemented. The underlying process that causes or worsens dyspnea must be treated and stabilized initially, then four additional therapies—pharmacological measures, oxygen therapy, physical techniques, and psychosocial techniques—are implemented. Pharmacological agents may include bronchodilators, steroids, mucolytics, and low-dose anti-anxiety medications. Oxygen therapy can reduce dyspnea associated with exercise. Physical techniques, such as cardiopulmonary reconditioning through exercise, breathing techniques, and cough control, can help to reduce dyspnea. Relaxation techniques, biofeedback, and meditation are physiological measures that the patient can use to help lessen the sensation of dyspnea.

Airway Maintenance. The airway is patent when the trachea, bronchi, and large airways are free from obstructions. Airway maintenance requires adequate hydration to prevent thick, tenacious secretions. Proper coughing techniques remove secretions and keep the airway open. A variety of interventions, such as suctioning, chest physiotherapy, and nebulizer therapy, assist the patient in managing alterations in airway clearance.

Mobilization of Pulmonary Secretions. The ability of a patient to mobilize pulmonary secretions may make the difference between a short-term illness and a long recovery involving complications. Nursing interventions that promote mobilization of pulmonary secretions help the patient to achieve and maintain a clear airway, and encourage lung expansion and gas exchange.

Humidification. Humidification is the process of adding water to gas. Temperature is the most important factor affecting the amount of water vapour a gas can hold. The percentage of water in the gas in relation to its capacity for water is the relative humidity. Air or oxygen with a high relative humidity keeps the airways moist and helps loosen and mobilize pulmonary secretions. Humidification is necessary for patients receiving oxygen therapy at >4 L/minute. Bubbling oxygen through water can add humidity to the oxygen delivered to the upper airways, as with a nasal cannula or face mask.

An oxygen hood is used for infants and a humidity tent is used for children with illnesses such as croup and tracheitis to liquefy secretions and assist in the reduction of fever (Hockenberry & Wilson, 2007). To prevent nonhumidified air or oxygen from entering the tent, the nebulizer at the top of the humidity tent remains filled with water. Air in the humidity tent can become cool and may fall below 20°C , thus causing the child to become chilled. Children in humidity tents require frequent changes of clothing and bed linen to remain dry and warm.

Nebulization. Nebulization is a process of adding moisture or medications to inspired air by mixing particles of varying sizes with the air. A nebulizer uses the aerosol principle to suspend a maximum number of water drops or particles of the desired size in inspired air. The moisture added to the respiratory system through nebulization improves clearance of pulmonary secretions. Nebulization is often used for administration of bronchodilators and mucolytic agents.

When the thin layer of fluid that supports the mucous layer over the cilia is allowed to dry, the cilia are damaged and cannot adequately clear the airway. Humidification through nebulization enhances mucociliary clearance, the body's natural mechanism for removing mucus and cellular debris from the respiratory tract.

► BOX 38-14

Guidelines for Chest Physiotherapy

Nursing care and selection of chest physiotherapy (CPT) skills are based on specific assessment findings. The following guidelines are designed to help in physical assessment and subsequent decision making:

- Know the patient's normal range of vital signs. Conditions such as atelectasis and pneumonia requiring CPT can affect vital signs. The degree of change is related to the level of hypoxia, overall cardiopulmonary status, and tolerance to activity.
- Know the patient's medications. Certain medications, particularly diuretics and antihypertensives, cause fluid and hemodynamic changes. These changes may decrease the patient's tolerance to the positional changes of postural drainage. Steroid medications increase the patient's risk of pathological rib fractures and often contraindicate rib shaking.
- Know the patient's medical history. Certain conditions such as increased intracranial pressure, spinal cord injuries, and abdominal aneurysm resection contraindicate the positional changes of postural drainage. Thoracic trauma or surgery may also contraindicate percussion, vibration, and rib shaking.
- Know the patient's level of cognitive function. Participation in controlled coughing techniques requires the patient to follow instructions. Congenital or acquired cognitive limitations may alter the patient's ability to learn and participate in these techniques.
- Be aware of the patient's exercise tolerance. CPT manoeuvres are fatiguing. When the patient is not used to physical activity, initial tolerance for the manoeuvres may be decreased. However, with gradual increases in activity and planned CPT, patient tolerance for the procedure will improve.

Chest Physiotherapy. Chest physiotherapy (CPT) is a group of therapies used in combination to mobilize pulmonary secretions. These therapies include postural drainage, chest percussion, and vibration. CPT should be followed by productive coughing and suctioning of the patient who has a decreased ability to cough. CPT is recommended for patients who produce greater than 30 mL of sputum per day or have evidence of atelectasis by chest X-ray examination. This procedure can be safely used with infants and young children; however, conditions and diseases unique to children may at times contraindicate this procedure. CPT is used for a select group of patients. Box 38-14 describes the guidelines for determining if CPT is indicated for the patient.

Chest percussion involves striking the chest wall over the area being drained. The hand is positioned so that the fingers and thumb touch and the hands are cupped (Figure 38-9). Percussion on the surface of the chest wall sends waves of varying amplitude and frequency through the chest, changing the consistency and location of the sputum. Chest percussion is performed by striking the chest wall alternately with cupped hands (Figure 38-10). Percussion is performed over a single layer of clothing, not over buttons, snaps, or zippers. The single layer of clothing prevents slapping the patient's skin. Thicker or multiple layers of material dampen the vibrations.

Percussion is contraindicated in patients with bleeding disorders, osteoporosis, or fractured ribs. It is important to percuss the lung fields and not the scapular regions, or trauma may occur to the skin and underlying musculoskeletal structures.

Figure 38-9 Hand position for chest wall percussion during chest physiotherapy.

Figure 38-10 Chest wall percussion, alternating hand clapping against the patient's chest wall.

Vibration is a fine, shaking pressure applied to the chest wall only during exhalation. This technique is thought to increase the velocity and turbulence of exhaled air, facilitating secretion removal. Vibration increases the exhalation of trapped air and may shake mucus loose and induce a cough.

Postural drainage is the use of positioning techniques that draw secretions from specific segments of the lungs and bronchi into the trachea. Coughing or suctioning normally removes secretions from the trachea. The procedure for postural drainage can include most lung segments (Table 38-8). Because patients may not require postural drainage of all lung segments, the procedure is based on clinical assessment findings. For example, patients with left lower lobe atelectasis may require postural drainage of only the affected region, whereas a child with cystic fibrosis may require postural drainage of all lung segments.

Suctioning Techniques. Suctioning is necessary when a patient is unable to clear respiratory tract secretions with coughing. The suctioning techniques include oropharyngeal and nasopharyngeal suctioning, orotracheal and nasotracheal suctioning, and suctioning of an artificial airway.

These techniques are based on common principles. In most cases, use sterile technique for suctioning because the trachea

is considered sterile. The mouth is considered clean, thus the suctioning of oral secretions should be performed after suctioning of the oropharynx and trachea. Each type of suctioning requires the use of a round-tipped catheter with a number of side holes at the distal end of the catheter. Frequency of suctioning is determined by patient assessment and need. If secretions are identified by inspection or auscultation techniques, suctioning is required. Because sputum is not produced continuously or every one or two hours but occurs as a response to a pathological condition, there is no rationale for routine suctioning of all patients every one to two hours. In addition, suctioning reduces the amount of the available dead space in the oropharynx and trachea, often resulting in significant desaturation. Be careful to monitor the patient to ensure

adequate oxygenation. Too-frequent suctioning can put the patient at risk for development of hypoxemia, hypotension, arrhythmias, and possible trauma to the mucosa of the lungs (Day et al., 2002).

Oropharyngeal and Nasopharyngeal Suctioning. The oropharynx extends behind the mouth from the soft palate above the level of the hyoid bone and contains the tonsils. The nasopharynx is located behind the nose and extends to the level of the soft palate. Oropharyngeal or nasopharyngeal suctioning is used when the patient is able to cough effectively but is unable to clear secretions by expectorating or swallowing. The suction procedure is used after the patient has coughed (Skill 38-1). As the amount of pulmonary secretions is reduced

► SKILL 38-1 Suctioning

video

Delegation Considerations

This skill may be delegated to nursing assistive personnel (NAP) in special situations. When you determine that the patient is stable, the skill of performing suctioning of an established tracheostomy can be delegated to a NAP when the patient has a permanent tracheostomy tube or is receiving home mechanical ventilation. Before delegating this skill, you must do the following:

- Discuss with the care provider any unique modifications of the skill, such as the need to reapply any supplemental oxygen equipment following the procedure.
- Appropriate suction limits.
- Instruct the NAP to report any change in the patient's respiratory status, signs and symptoms of hypoxemia, secretion colour or volume, or unresolved coughing or gagging.
- Instruct the NAP to report any change in patient's colour, vital signs, or pain level.

Equipment

- Appropriate-size suction catheter (smallest diameter that will remove secretions effectively) or Yankauer catheter (oral suction)
- Nasal or oral airway (if indicated)
- Two sterile gloves or one sterile and one clean disposable glove (refer to technique)
- Clean towel or paper drape
- Portable or wall suction
- Mask, goggles, or face shield
- Connecting tube (1.8 metres)
- Pulse oximeter and stethoscope

Equipment for Procedure Without Closed-Suction Catheter

- Small Y adapter (if catheter does not have a suction-control port)
- Water-soluble lubricant
- Sterile basin
- Sterile normal saline solution or water (approximately 100 mL)

Procedure

STEPS

1. Assess for signs and symptoms of upper and lower airway obstruction requiring nasotracheal or orotracheal suctioning, abnormal respiratory rate, adventitious sounds, nasal secretions, gurgling, drooling, restlessness, gastric secretions, or vomitus in mouth, and coughing without clearing secretions from airway.
2. Assess signs and symptoms associated with hypoxia and hypercapnia: decreased SpO₂, increased pulse and blood pressure, increased respiratory rate, apprehension, anxiety, decreased ability to concentrate, lethargy, decreased level of consciousness (especially acute), increased fatigue, dizziness, behavioural changes (especially irritability), dysrhythmias, pallor, and cyanosis.
3. Determine factors that normally influence upper or lower airway functioning:
 - Fluid status
 - Lack of humidity
 - Pulmonary disease, chronic obstructive pulmonary disorder, pulmonary infection

RATIONALE

- Physical signs and symptoms result from decreased oxygen to tissues, as well as pooling of secretions in upper and lower airways. Complete assessment before and after suction procedure (American Association of Respiratory Care [AARC], 2004; Demir & Dramali, 2005).
- Physical signs and symptoms resulting from decreased oxygen to tissues indicate need for suctioning. Anxiety and pain consume oxygen and, in turn, worsen the signs of hypoxia (Considine, 2005).
- Fluid overload may increase amount of secretions. Dehydration promotes thicker secretions.
- The environment influences secretion formation and gas exchange, necessitating airway suctioning when the patient cannot clear secretions effectively.
- Increases patient's risk for retaining pulmonary secretions. Patients with respiratory infections are prone to increased secretions that are thicker and sometimes more difficult to expectorate.

Continued

► SKILL 38-1 Suctioning—cont'd

- Anatomy
 - Changes in level of consciousness
 - Decreased cough or gag reflex
 - Allergies, sinus drainage
4. Identify contraindications to nasotracheal suctioning: occluded nasal passages; nasal bleeding, epiglottitis, or croup; acute head, facial, or neck injury or surgery, coagulopathy, or bleeding disorder; irritable airway or laryngospasm or bronchospasm; gastric surgery with high anastomosis; myocardial infarction (AARC, 2004).
 5. Examine sputum microbiology data.
 6. Assess patient's understanding of the procedure.
 7. Obtain physician's order if indicated by agency policy.
 8. Explain to patient how the procedure will help clear the airway and relieve breathing problems and that temporary coughing, sneezing, gagging, or shortness of breath is normal. Encourage patient to cough out secretions. Have patient practise coughing, if able. Splint surgical incisions, if necessary.
 9. Explain the importance of coughing and encourage coughing during procedure.
 10. Help patient to assume a position comfortable for you and the patient (usually semi-Fowler's or sitting upright with head hyperextended, unless contraindicated).
 11. Place pulse oximeter on patient's finger. Take reading and leave pulse oximeter in place.
 12. Place towel across patient's chest.
 13. Perform hand hygiene. Apply mask, goggles, or face shield if splashing is likely.
 14. Connect one end of connecting tubing to suction machine and place the other end in a convenient location near patient. Turn suction device on and set vacuum regulator to appropriate negative pressure: preterm infants 60–80 mm Hg, infants 80–100 mm Hg, children 100–120 mm Hg, adults 100–150 mm Hg (AARC, 2004, p. 1080). **Appropriate pressure may vary; check institutional policy.**
 15. If indicated, increase supplemental oxygen therapy to 100% or as ordered by physician. Encourage patient to deep-breathe.
 16. Preparation for all types of suctioning:
 - A. Open suction kit or catheter with use of aseptic technique. If a sterile drape is available, place it across the patient's chest or on the overbed table. Do not allow the suction catheter to touch any nonsterile surfaces.
- Abnormal anatomy can impair normal drainage of secretions. For example, nasal swelling, a deviated septum, or facial fractures may impair nasal drainage. Tumours in or around the lower airway may impair secretion removal by occluding or externally compressing the lumen of the airway.
 - Impairs patient's ability to cough independently or follow instructions to cough and clear airway.
 - Increases patient's risk for aspiration and subsequent pulmonary infection.
 - Increases volume of secretions in pharynx.
 - These conditions are contraindicated because the passage of the catheter through the nasal route causes trauma to existing facial trauma or surgery, increases nasal bleeding, or causes severe bleeding in the presence of bleeding disorders. With epiglottitis, croup, laryngospasm, or irritable airway, the entrance of a suction catheter via the nasal route causes intractable coughing, hypoxemia, and severe bronchospasm, necessitating emergency intubation or tracheostomy (Moore, 2003).
 - Certain bacteria are easier to transmit or require isolation because of virulence or antibiotic resistance.
 - Reveals need for patient instruction and encourages cooperation.
 - Some institutions require a physician's order for tracheal suctioning.
 - Encourages cooperation and minimizes risks, anxiety, and pain.
 - Facilitates secretion removal and may reduce frequency and duration of future suctioning.
 - Reduces stimulation of gag reflex, promotes patient comfort and secretion drainage, and prevents aspiration. Position lessens strain on the nurse's back. Hyperextension facilitates insertion of the catheter into the trachea.
 - Provides baseline oxygen level to determine patient's response to suctioning.
 - Reduces transmission of microorganisms by protecting gown from secretions.
 - Reduces transmission of microorganisms.
 - Excessive negative pressure damages nasal pharyngeal and tracheal mucosa and induces greater hypoxia.
 - Hyperoxygenation provides some protection from suction-induced decline in oxygenation. Hyperoxygenation is most effective in the presence of hyperinflation, such as when encouraging the patient to deep-breathe or to increase ventilator tidal volume settings (Demir & Dramali, 2005).
 - Prepares catheter and prevents transmission of microorganisms. A sterile drape provides sterile surface on which to lay the suction catheter between passes, if needed.

SKILL 38-1 Suctioning—cont'd

- B. Unwrap or open sterile basin and place on bedside table. Fill basin or cup with approximately 100 mL of sterile normal saline solution or water (see Step 16B illustration).

Step 16B Pouring sterile saline into basin.

- C. Turn on suction device. Set regulator to appropriate negative pressure: 100–150 mm Hg for adults (AARC, 2004).

17. Suction airway.

A. Oropharyngeal suctioning

- (1) Apply clean disposable gloves and mask or face shield (if splashing is likely).
 - (2) Attach suction catheter to connecting tubing. Check that equipment is functioning properly by suctioning a small amount of water or normal saline from the cup or basin.
 - (3) Remove oxygen mask if present. Keep oxygen mask near patient's face. Nasal cannula may remain in place (if present).
- Normal saline or water to flush catheter and tubing after each suction pass.
 - Suction of oral cavity does not require use of sterile gloves. Suction may cause splashing of body fluids.
 - Allows access to patient's mouth. Reduces chances of hypoxia.

Critical Decision Point: Be prepared to quickly reapply oxygen mask if SpO_2 falls or respiratory distress develops during or at the end of suctioning (Considine, 2005; Pease, 2006).

- (4) Insert catheter into the patient's mouth. With suction applied, move catheter around mouth, including pharynx and gum line, until secretions are cleared.
 - (5) Encourage patient to cough, and repeat suctioning if needed. Replace oxygen mask if used.
 - (6) Suction water from basin through catheter until catheter is cleared of secretions. Turn off suction.
 - (7) Place catheter in a clean, dry area for reuse.
- Movement of catheter prevents suction tip from invaginating oral mucosal surfaces, thus potentially causing trauma.
 - Coughing moves secretions from lower to upper airways into mouth.
 - Clearing secretions before they dry reduces the probability of transmission of microorganisms and enhances delivery of preset suction pressures.
 - Facilitates prompt removal of airway secretions when suctioning is needed in the future. Moist environment encourages microorganism growth.

Critical Decision Point: Keep catheter in nonairtight container such as brown paper or plastic bag attached to bed rail or in suction canister area. Do not store the catheter where it will come in contact with secretions or excretions, which promote bacterial growth.

B. Nasopharyngeal and nasotracheal suctioning

- (1) Open lubricant. Squeeze small amount onto open sterile catheter package without touching package. Lubricant is not necessary for artificial airway suctioning.
 - (2) Apply sterile glove to each hand, or apply nonsterile glove to nondominant hand and sterile glove to dominant hand.
- Prepares lubricant while maintaining sterility. Water-soluble lubricant is used to avoid lipoid aspiration pneumonia. Excessive lubricant can occlude the catheter.
 - Reduces transmission of microorganisms and allows nurse to maintain sterility of suction catheter.

Continued

► SKILL 38-1 Suctioning—cont'd

video

- (3) Pick up suction catheter with dominant hand without touching nonsterile surfaces. Pick up connecting tubing with nondominant hand. Secure catheter to tubing (see Step 17B[3] illustration).

Step 17B(3) Attaching catheter to suction.

- (4) Check that the equipment is functioning properly by suctioning a small amount of normal saline solution from the basin.
- (5) Lightly coat distal 6–8 cm of catheter with water-soluble lubricant.
- (6) Remove oxygen delivery device, if applicable, with nondominant hand. *Without applying suction* and using dominant thumb and forefinger, gently insert catheter into naris during inhalation.
- (7) *Nasopharyngeal*: Follow natural course of naris; slightly slant catheter downward and advance to back of pharynx. In adults, insert catheter about 16 cm; in older children, 8–12 cm; in infants and young children, 4–8 cm. The rule of thumb is to insert catheter a distance from tip of nose (or mouth) to angle of mandible.
- (a) Apply intermittent suction for 10–15 seconds by placing and releasing nondominant thumb over catheter vent. Slowly withdraw catheter while rotating it back and forth between thumb and forefinger.
- (8) *Nasotracheal*: Follow natural course of naris and advance catheter slightly slanted and downward to just above entrance into trachea. Allow patient to take a breath. Quickly insert catheter approximately 20 cm (in adult) into trachea (see Step 17B[8] illustration). Patient will begin to cough. *Note*: In older children, advance 16–20 cm; in young children and infants, 8–14 cm.
- Maintains catheter sterility. Connects catheter to suction.
 - Ensures equipment function; lubricates catheter and tubing.
 - Lubricates catheter for easier insertion.
 - Application of suction pressure while introducing catheter into nasopharyngeal tissues increases risk of damage to mucosa. When advanced into trachea, suction could damage mucosa and increase risk of hypoxia.
 - Proper placement ensures removal of pharyngeal secretions.
 - Intermittent suction safely removes pharyngeal secretions. Suction time of >15 seconds increases risk for suction-induced hypoxemia (Oh & Seo, 2003).
 - Ensures catheter will be inserted into trachea.

Step 17B(8) Distance of insertion of nasotracheal catheter.

► SKILL 38-1 Suctioning—cont'd

Critical Decision Point: Insert catheter during patient inhalation, especially if inserting catheter into trachea because epiglottis is open. *Do not insert during swallowing* or catheter will most likely enter the esophagus. *Never* apply suction during insertion. Patient should cough. If patient gags or becomes nauseated, catheter is most likely in the esophagus and must be removed.

- (a) *Positioning option for nasotracheal suctioning:* In some instances, turning the patient's head to the right will help you suction the left mainstem bronchus; turning head to the left will help you suction the right mainstem bronchus. If resistance is felt after insertion of catheter for maximum recommended distance, the catheter has probably hit carina. Pull the catheter back 1–2 cm before applying suction.
 - Turning the patient's head to the side elevates the bronchial passage on the opposite side and facilitates passage of the catheter.

Critical Decision Point: Use nasal approach and perform tracheal suctioning before pharyngeal suctioning whenever possible. The mouth and pharynx contain more bacteria than the trachea does. If copious oral secretions are present before beginning the procedure, suction the mouth with an oral suction device.

- (b) Apply intermittent suction for 10–15 seconds by placing and releasing nondominant thumb over vent of catheter and slowly withdrawing catheter while rotating it back and forth between dominant thumb and forefinger. Encourage patient to cough. Replace oxygen device, if applicable.
 - Intermittent suction and rotation of catheter prevent injury to mucosa. If the catheter “grabs” mucosa, remove thumb to release suction. Suctioning longer than 15 seconds can cause cardiopulmonary compromise, usually from hypoxemia or vagal overload.

Critical Decision Point: If ordered to monitor patient's vital signs and oxygen saturation during the procedure, note if the patient's pulse drops more than 20 beats per minute or increases more than 40 beats per minute, or oxygen saturation falls below 90% or 5% from baseline, in which case cease suctioning (Lindgren & Ames, 2005).

- (9) Rinse catheter and connecting tubing with normal saline or water until cleared.
 - Removes secretions from catheter. Secretions that remain in suction catheter or connecting tubing decrease suctioning efficiency.
 - (10) Assess for need to repeat suctioning procedure. Do not perform more than two passes with the catheter. Allow adequate time (at least one minute) between suction passes for ventilation and oxygenation (AARC, 2004). Ask patient to deep-breathe and to cough.
 - Observe for alterations in cardiopulmonary status. Suctioning can induce hypoxemia, dysrhythmias, laryngospasm, and bronchospasm. Deep breathing reventilates and reoxygenates alveoli and reduces the risk for suction-induced hypoxemia (Bourgault et al., 2006). Repeated passes clear the airway of excessive secretions but can also remove oxygen and may induce laryngospasm.
- C. Artificial airway suctioning
- (1) Apply face shield.
 - Reduces transmission of microorganisms.
 - (2) Apply one sterile glove to each hand, or apply nonsterile glove to nondominant hand and sterile glove to dominant hand.
 - Reduces transmission of microorganisms and allows nurse to maintain sterility of suction catheter.
 - (3) Pick up suction catheter with dominant hand without touching nonsterile surfaces. Pick up connecting tubing with nondominant hand. Secure catheter to tubing.
 - Maintains catheter sterility. Establishes suction.
 - (4) Check that equipment is functioning properly by suctioning a small amount of saline from the basin.
 - Ensures equipment function; lubricates catheter and tubing.
 - (5) Hyperinflate or hyperoxygenate patient, or do both, before suctioning, using manual resuscitation bag-valve device connected to oxygen source on mechanical ventilator. Some mechanical ventilators have a button that, when pushed, delivers oxygen for a few minutes and then resets to the previous value.
 - Hyperinflation decreases risk for atelectasis caused by negative pressure of suctioning (Demir & Dramali, 2005). Preoxygenation converts a large proportion of resident lung gas to 100% oxygen to offset the amount used in metabolic consumption while ventilator or oxygenation is interrupted, and to offset volume lost during suction procedure (Bourgault et al., 2006).

Critical Decision Point: Suctioning can cause elevations in intracranial pressure (ICP) in patients with head injuries. Reduce this risk by presuction hyperventilation, which results in hypocarbia, thus inducing vasoconstriction. Vasoconstriction reduces the potential for an increase in ICP. Limit suctioning to two times with each suctioning procedure (Considine, 2005; Demir & Dramali, 2005).

- (6) If patient is receiving mechanical ventilation, open swivel adapter or, if necessary, remove oxygen or humidity delivery device with nondominant hand.
 - Exposes artificial airway.

Continued

► SKILL 38-1 Suctioning—cont'd

- (7) Without applying suction, gently but quickly insert catheter using dominant thumb and forefinger into artificial airway (it is best to time catheter insertion with inspiration) until resistance is met or patient coughs, then pull back 1 cm.

- Application of suction pressure while introducing catheter into the trachea increases risk of damage to tracheal mucosa and greater hypoxia through removal of entrained oxygen present in airways. The action of pulling back stimulates cough and removes catheter from mucosal wall so that catheter is not resting against tracheal mucosa during suctioning.

Critical Decision Point: If unable to insert catheter past the end of the endotracheal tube, the catheter is probably caught in the Murphy eye (i.e., side hole at the distal end of the endotracheal tube that allows for collateral airflow in the event of main stem intubation) (Lindgren & Ames, 2005). If this happens, rotate catheter to reposition it away from the Murphy eye, or withdraw it slightly and reinsert with the next inhalation. Usually the catheter meets resistance at the carina. One indication that the catheter is at the carina is acute onset of coughing, because the carina contains many cough receptors. The catheter should be pulled back 1 cm.

- (8) Apply intermittent suction by placing and releasing nondominant thumb over vent of catheter; slowly withdraw catheter while rotating it back and forth between dominant thumb and forefinger (see Step 17C[8] illustration). Encourage patient to cough. Watch for respiratory distress.

- Intermittent suction and rotation of catheter prevent injury to tracheal mucosal lining. If catheter “grabs” mucosa, remove thumb to release suction.

Step 17C(8) Suctioning tracheostomy.

Critical Decision Point: If patient develops respiratory distress during suction procedure, immediately withdraw catheter and supply additional oxygen and breaths as needed. Oxygen can be administered directly through the catheter in an emergency. Disconnect suction and attach oxygen at prescribed flow rate through the catheter.

- (9) If patient is receiving mechanical ventilation, close swivel adapter or replace oxygen delivery device.
- (10) Encourage patient to deep-breathe, if able. Some patients respond well to several manual breaths from the mechanical ventilator or bag-valve device.
- (11) Rinse catheter and connecting tubing with normal saline until clear. Use continuous suction.
- (12) Assess patient's cardiopulmonary status for secretion clearance and complications. Repeat Steps 17C(5) through 17C(11) once or twice more to clear secretions. Allow adequate time (at least one full minute) between suction passes for ventilation and reoxygenation. Perform oropharyngeal suctioning to clear mouth of secretions (Steps 17A, 17B). Do not suction nose again after suctioning mouth.
18. Complete procedure:
- Disconnect catheter from connecting tubing. Roll catheter around fingers of dominant hand. Pull glove off inside out so that catheter remains in glove. Pull off other glove over first glove in same way to contain contaminants. Discard into appropriate receptacle.
 - Remove towel and place in laundry or remove drape and discard in appropriate receptacle.
- Re-establishes the artificial airway.
 - Reoxygenates and re-expands alveoli. Suctioning can cause hypoxemia and atelectasis.
 - Removes catheter secretions. Secretions left in tubing decrease suction and provide environment for microorganism growth. Secretions left in connecting tube decrease suctioning efficiency.
 - Suctioning can induce dysrhythmias, hypoxia, and bronchospasm and impair cerebral circulation or adversely affect hemodynamics (Demir & Dramali, 2005; Lindgren & Ames, 2005).
 - The upper airway is considered clean and lower airway is considered sterile. Therefore, the same catheter can be used to suction from sterile to clean areas, but not from clean to sterile areas.
 - Reduces transmission of microorganisms. Clean equipment should not be touched with contaminated gloves.

► SKILL 38-1 Suctioning—cont'd

- C. Reposition patient as indicated by condition. You may need to reapply clean gloves for patient's personal care (e.g., oral hygiene).
 - D. If indicated, readjust oxygen to original level.
 - E. Discard remainder of normal saline into appropriate receptacle. If basin is disposable, discard into appropriate receptacle. If basin is reusable, rinse and place in soiled utility room.
 - F. Remove and discard face shield, and perform hand hygiene.
 - G. Place unopened suction kit on suction machine table or at head of bed according to institution preference.
19. Compare patient's vital signs and SpO₂ saturation before and after suctioning.
 20. Ask patient if breathing is easier and if congestion is decreased.
 21. Observe airway secretions.
- Proper positioning based on patient's condition promotes comfort, encourages secretion drainage, and reduces risk of aspiration.
 - Helps patient's blood oxygen level return to baseline.
 - Solution is contaminated.
 - Reduces transmission of microorganisms.
 - Provides for immediate access of suction catheter and equipment in the event of an emergency or for the next suctioning procedure.
 - Identifies physiological effects of suction procedure to restore airway patency.
 - Provides subjective confirmation that airway obstruction is relieved with suctioning procedure.
 - Provides data to document presence or absence of respiratory tract infection.

Unexpected Outcomes

Worsening respiratory status

Return of bloody secretions

Unable to pass suction catheter through first naris attempted

Paroxysms of coughing

No secretions obtained

Related Interventions

- Limit length of suctioning.
- Determine need for more frequent suctioning, possibly of shorter duration.
- Determine need for supplemental oxygen, supply oxygen between suction passes.
- Notify physician.
- Determine amount of suction pressure used. It may need to be decreased.
- Ensure suction completed correctly by using intermittent suction and rotation of catheter.
- Evaluate suctioning frequency.
- Provide more frequent oral hygiene.
- Try other naris or oral route.
- Insert nasal airway, especially if suctioning through patient naris frequently.
- Guide catheter along naris floor to avoid turbinates.
- If obstruction is mucus, apply suction to relieve obstruction, but do not apply suction to mucosa. If obstruction is thought to be a blood clot, consult physician.
- Increase lubrication of catheter.
- Administer supplemental oxygen.
- Allow patient to rest between passes of suction catheter.
- Consult physician regarding need for inhaled bronchodilators or topical anaesthetics.
- Evaluate patient's fluid status.
- Assess for signs of infection.
- Determine need for chest physiotherapy.
- Assess adequacy of humidification on oxygen delivery device.

Recording and Reporting

- Record the amount, consistency, colour, and odour of secretions and patient's response to procedure; document patient's pre-suctioning and post-suctioning cardiopulmonary status.

Home Care Considerations

- You need to adhere to best practices for infection control while weighing cost-effectiveness in the setting of a chronic situation. If the patient has an established tracheostomy or requires long-term nasotracheal suctioning and infection is not present, clean suction technique is appropriate.
- Instruct the patient and family in infection-control measures for emptying the secretion jar. These secretions should be emptied in the toilet but they have a splash risk. Instruct the caregiver to apply a mask (shield if available) and gloves and bring the secretion jar as close to the toilet bowl as possible to decrease the risk of splash.

and the patient is less fatigued, the patient may be able to expectorate or swallow the mucus, and suctioning is no longer required.

Orotracheal and Nasotracheal Suctioning. Orotracheal or nasotracheal suctioning is necessary when the patient with pulmonary secretions is unable to manage secretions by coughing and does not have an artificial airway (see Skill 38-1). A catheter is passed through the mouth or nose into the trachea. The nose is the preferred route because stimulation of the gag reflex is minimal. The procedure is similar to nasopharyngeal suctioning, but the catheter tip is moved farther into the patient's trachea. The entire procedure from catheter passage to its removal should be done quickly, lasting no longer than 15 seconds (American Association of Respiratory Care [AARC], 2004). Unless in respiratory distress, the patient should be allowed to rest between passes of the catheter. If the patient is using supplemental oxygen, the oxygen cannula or mask should be replaced during rest periods.

Tracheal Suctioning. Tracheal suctioning is accomplished through an artificial airway such as an endotracheal tube or tracheostomy tube (see Skill 38-1). The suction catheter should be no greater than one-half the size of the internal diameter of the artificial airway (Moore, 2003). Secretion removal should be as atraumatic as possible. To avoid trauma to the mucosa of the lung, never apply suction pressure while inserting the catheter, and maintain suction pressure between 100 and 150 mm Hg (AARC, 2004). Apply suction intermittently as the catheter is withdrawn. Rotating the catheter will enhance removal of secretions that have adhered to the sides of the endotracheal tube. Apply a mask and goggles, and wear a barrier gown to prevent splashes with body fluids.

The practice of normal saline instillation (NSI) into artificial airways to improve secretion removal is inconclusive. Clinical studies comparing suctioning after NSI with standard suctioning have not demonstrated any clinical or significant results (Celik & Kanan, 2006). More recently, some clinicians have recommended that instillation of isotonic sodium chloride before suctioning of an endotracheal tube not be used as routine or standard clinical practice (Akgul & Kanan, 2006). There are anecdotal results supporting the theory that NSI stimulates the patient to cough, thus loosening and dislodging the airway secretions. However, the practice of NSI via an endotracheal tube may decrease oxygen saturation, increase intracranial pressure and arterial blood pressure, and cause cardiac dysrhythmias, cardiac arrest, respiratory arrest, and nosocomial infection (Akgul & Kanan, 2006). The use of isotonic normal saline with suctioning has the potential to increase ventilator-associated pneumonia as bacteria can move from the upper to lower airway (Celik & Kanan, 2006; Grap & Munro, 2004).

The two current methods of suctioning are the open and closed methods. Open suctioning involves a sterile catheter that is opened at the time of suctioning. Wear sterile gloves to perform the suction procedure. Closed suctioning involves a multiple-use suction catheter encased in a plastic sheath (Figure 38-11). Closed suctioning is most often used on patients who require mechanical ventilation to support their respiratory efforts, because it permits continuous delivery of oxygen while suction is performed, thus reducing the risk of oxygen desaturation. Although sterile gloves are not required in this procedure, at least nonsterile (i.e., disposable) gloves are recommended to prevent contact with splashes from body fluids.

Figure 38-11 Ballard tracheal care, closed suction.

Figure 38-12 Artificial oral airways.

Artificial Airways. An artificial airway is indicated for patients with a decreased level of consciousness or an airway obstruction and to aid in the removal of tracheobronchial secretions.

Oral Airway. The oral airway, the simplest type of artificial airway, prevents obstruction of the trachea by displacement of the tongue into the oropharynx (Figure 38-12). The oral airway extends from the teeth to the oropharynx, maintaining the tongue in the normal position. The correct-size airway must be used. Proper oral airway size is determined by measuring the distance from the corner of the mouth to the angle of the jaw just below the ear. The length is equal to the distance from the flange of the airway to the tip. If the airway is too small, the tongue is not held in the anterior portion of the mouth; if the airway is too large, it may force the tongue toward the epiglottis and obstruct the airway.

Insert the airway by turning the curve of the airway toward the cheek and placing it over the tongue. When the airway is in the oropharynx, turn it so that the opening points downward. When correctly placed, the airway moves the tongue forward away from the oropharynx, and the flange, the flat portion of the airway, rests against the patient's teeth. Incorrect insertion merely forces the tongue back into the oropharynx.

Endotracheal and Tracheal Airway. The presence of an artificial airway places the patient at high risk for infection and

airway injury. Use sterile technique in caring for and maintaining an artificial airway to prevent nosocomial infections. Artificial airways need to be cared for and maintained in the correct position to prevent airway damage (Skill 38-2).

Endotracheal (ET) tubes are used as short-term artificial airways to administer mechanical ventilation, relieve upper airway obstruction, protect against aspiration, or clear secretions. ET tubes are generally removed within 14 days; however, they may be used for a longer period of time if the patient is showing progress toward weaning from mechanical ventilation and extubation.

If the patient requires long-term assistance from an artificial airway, a tracheostomy is considered. A surgical incision is

made into the trachea, and a short artificial airway (a tracheostomy tube) is inserted.

Maintenance and Promotion of Lung Expansion.

Nursing interventions to maintain or promote lung expansion include noninvasive and invasive techniques. Noninvasive techniques are positioning and incentive spirometry. An invasive procedure is management of a chest tube.

Positioning. In the healthy, completely mobile person, adequate ventilation and oxygenation are maintained by frequent position changes during daily activities. However, when a person's illness or injury restricts mobility, there is an increased risk for respiratory impairment. Frequent changes of

Text continued on p. 920

video

Delegation Considerations

This skill should not be routinely delegated to nursing assistive personnel (NAP). It is your responsibility to perform endotracheal care. In some settings, patients who have well-established tracheostomy tubes may have the care delegated to NAPs. It is your responsibility to assess and ensure that proper artificial airway care is provided. In addition, NAPs may perform other aspects of the patient's care. You must instruct the NAP about the following:

- To report any changes in the patient's respiratory status, level of consciousness, confusion, restlessness, irritability, or pain
- To report abnormal colour of tracheal stoma and drainage
- Emergency procedures in case the tracheostomy tube inadvertently becomes dislodged when ties are changed

Equipment

Endotracheal (ET) Tube Care

- Towel
- ET and oropharyngeal suction equipment
- 2.5 to 3 cm adhesive or waterproof tape (not paper or silk tape) or commercial ET tube holder and mouthguard (follow manufacturer's instructions for securing)
- Two pairs of disposable (nonsterile) gloves
- Adhesive remover swab or acetone on a cotton ball
- Mouth care supplies (e.g., toothbrush, toothpaste, nonalcoholic mouthwash)
- Face cleanser (e.g., wet washcloth, towel, soap, shaving supplies)
- Clean 2 × 2 gauze
- Tincture of benzoin, liquid adhesive, or skin prep pads
- Mask, goggles, face shield (if indicated)
- Stethoscope

Tracheostomy Care

- Towel
- Tracheostomy suction supplies
- Sterile tracheostomy care kit, if available, or two sterile 4 × 4 gauze pads
- Sterile cotton-tipped applicators
- Sterile tracheostomy dressing
- Sterile basin
- Small sterile brush (or disposable cannula)
- Tracheostomy ties (e.g., twill tape, manufactured tracheostomy ties, Velcro tracheostomy ties)
- Normal saline (NS)
- Scissors
- Two sterile gloves
- Mask, goggles, face shield (if indicated)

Procedure

STEPS

1. Perform pulmonary assessment:
 - A. Auscultate lung sounds.
 - B. Assess condition and patency of airway and surrounding tissues.
 - C. Note type and size of tube, movement of tube, and cuff size.

RATIONALE

- Provides baseline information.
- Indicates if additional skin care to irritated areas is needed. Identifies potential pressure areas.
- Movement of tube predisposes the patient to tracheal trauma or tube dislodgement and may indicate the need for another size airway. Cuff size indicates the amount of air needed to properly inflate cuff.

Continued

► SKILL 38-2 Care of an Artificial Airway—cont'd

2. Explain procedure to the patient and family.
3. Position patient: Usually supine or semi-Fowler's.
4. Place towel across patient's chest.
5. Perform hand hygiene. Apply mask, goggles, or face shield (if indicated).
6. Perform airway care.
 - A. Endotracheal tube care
 - (1) Observe for signs and symptoms of need to perform care of the artificial airway:
 - (a) Soiled or loose tape
 - (b) Pressure sores on nares, lip, or corner of mouth
 - (c) Unstable tube
 - (d) Excessive secretions
 - (2) Identify factors that increase the risk of complications from ET tubes:
 - (a) Type and size of tube
 - (b) Movement of tube up and down trachea
 - (c) Cuff size
 - (d) Duration of placement
 - (3) Determine proper ET tube depth as noted by centimetres at lip or gum line. This line is marked on the tube and recorded in the patient's record at time of intubation.
 - (4) Suction ET tube (see Skill 38-1):
 - Reinforces information given to patient and family and provides an opportunity for them to ask additional questions.
 - Provides access to the site and facilitates completion of the procedure.
 - Reduces transmission of microorganisms and protects linens and bedclothes.
 - Reduces transmission of microorganisms.
 - A patient with an artificial airway is at increased risk because of the inability to control secretions or difficulty in controlling them, and because of pressure points of the artificial airway.
 - A tube moving up and down the trachea predisposes the patient to tracheal trauma or dislodgement. Cuff underinflation may allow aspiration, whereas overinflation causes tracheal mucosa injury (Hess, 2005).
 - Ensures that tube is a proper depth to adequately ventilate both lungs and that tube is not too high (causing vocal cord damage) or too low (causing right main-stem intubation thus ventilating only right lung).
 - Removes secretions. Diminishes patient's need to cough during procedure.

Critical Decision Point: An oral airway should be immediately accessible in the event that the patient bites down and obstructs the ET tube.

- (a) Instruct patient not to bite or move ET tube with tongue or pull on tubing; removal of tape can be uncomfortable.
- (b) Leave Yankauer suction catheter connected to suction source.
- (5) Prepare method to secure endotracheal tube (check agency policy).
 - (a) *Tape method:* Cut piece of tape long enough to go completely around patient's head from naris to naris plus 15 cm; for an adult, approximately 30–60 cm. Lay adhesive side up on bedside table. Cut and lay 8–15 cm of tape, adhesive side down, in centre of long strip to prevent tape from sticking to hair.
 - (b) *Commercially available endotracheal tube holder:* Open package per manufacturer's instructions. Set device aside with the head guard in place and the Velcro strips open.
- (6) Apply clean gloves, and instruct assistant to apply gloves and hold ET tube firmly at patient's lips. Note the number marking on the ET tube at the gum line.
 - Prepares patient for procedure and what to expect.
 - Prepares for oropharyngeal suctioning.
 - Adhesive tape must be placed around the head from cheek to cheek below the ears. Avoid placing it over the ears, as this may result in a pressure sore.
 - Commercial devices are latex-free, fast, and convenient.
 - Reduces transmission of microorganisms. Maintains proper tube position and prevents accidental extubation.

Critical Decision Point: Do not allow helper to hold the tube away from the lips or nares. Doing so allows too much "play" in the tube and increases the risk for tube movement and accidental extubation. Never let go of the ET tube because the tube could become dislodged.

- (7) Remove old tape or device.
 - (a) *Tape:* Carefully remove tape from ET tube and patient's face. If tape is difficult to remove, moisten it with (soapy) wet washcloth, water, or adhesive tape remover. Discard tape in appropriate receptacle if nearby. If not, place soiled tape on bedside table or on distant end of towel.
 - (b) *Commercially available device:* Remove Velcro strips from ET tube, and remove ET tube holder from patient.
 - Provides access to skin under tape for assessment and hygiene. Reduces transmission of microorganisms.
 - The Velcro adhesive strips hold the ET tube in place and provide a marker to measure distance to patient's lips or gums. These devices permit access to patient's mouth and lips for ease in oropharyngeal suctioning and oral hygiene.

► SKILL 38-2 Care of an Artificial Airway—cont'd

- (8) Remove excess secretions or adhesive left on patient's face. Use adhesive remover swab to remove excess adhesive left on face after tape removal. Wash adhesive remover from face.
- (9) Remove oral airway or bite block if present.
- Promotes hygiene. Retained adhesive can cause damage to skin and prevent adhesion of new tape.
- Provides access and complete observation of patient's oral cavity.

Critical Decision Point: Do not remove oral airway if patient is actively biting. Wait until tape or device is partially or completely secured to ET tube.

- (10) Clean mouth, gums, and teeth opposite ET tube with nonalcoholic-based mouthwash solution and toothpaste on toothbrush or toothette. Brush teeth as indicated. If necessary, administer oropharyngeal suctioning with Yankauer catheter.
- (11) Note "cm" ET tube (oral ET tube only) marking at lips or gums. With help of assistant, move ET tube to opposite side or centre of mouth. Do not change tube depth (Vollman, 2006).
- (12) Repeat oral cleaning as in Step (9) on opposite side of mouth.
- (13) Clean face and neck with soapy washcloth; rinse and dry. Shave male patient as necessary.
- (14) Use small amount of skin protectant or liquid adhesive on clean 2 × 2 gauze and dot on upper lip (oral ET tube) or across nose (nasal ET tube) and cheeks to ear. Allow to dry completely.
- (15) Secure ET tube.
 - (a) *Tape method:*
 - (a1) Slip tape under patient's head and neck, adhesive side up. Do not twist tape or catch hair, or allow tape to stick to itself. It helps to stick tape gently to the tongue blade, which serves as a guide as tape is passed behind the patient's head. Centre tape so that double-faced tape extends around the back of the neck from ear to ear.
 - (a2) On one side of face, secure tape from ear to naris (nasal ET tube) or over lip to ET tube (oral ET tube). Tear remaining tape in half lengthwise, forming two pieces that are 1–2 cm wide. Secure bottom half of tape across upper lip (oral ET tube) or across top of nose (nasal ET tube; see Step 6A[15][a2] illustration, part A). Wrap top half of tape around tube (see Step 6A[15][a2] illustration, part B). Tape should encircle tube at least two times for security.
- Provides oral hygiene and allows for observation of any pressure ulcers. Alcohol-based mouthwashes dry oral mucosa (Lewis et al., 2010). Suctioning removes pooled secretions.
- Prevents formation of pressure sores at sides of patient's mouth. Ensures correct position of tube and allows for quick visual scan of displaced tube. Measuring the tube at the lip line can be distorted due to edema, trauma, or disease process (Vollman, 2006).
- Removes secretions from mouth and oropharynx.
- Moisture and beard growth prevent adhesive tape adherence.
- Protects and makes skin more receptive to tape.
- Positions tape to secure ET tube in proper position.
- Secures tape to face. Using top tape to wrap tube prevents downward drag on ET tube.

Step 6A(15)(a2) A, Securing bottom half of tape across patient's upper lip. B, Securing top half of tape around tube.

Continued

► SKILL 38-2 Care of an Artificial Airway—cont'd

video

- (a3) Gently pull other side of tape firmly to pick up slack, and secure it to remaining side of face (see Step 6A[15][a3] illustration). Have assistant release hold when tube is secure. You may want the assistant to help reinsert the oral airway.

Step 6A(15)(a3) Tape securing ET tube.

(b) Commercially available device:

- (b1) Place ET tube through opening designed to secure ET tube. Ensure that pilot balloon to the ET tube is accessible.
 - (b2) Place Velcro strips of ET holder under patient at occipital region of the head.
 - (b3) Verify that ET tube is at the established position using the lip or gum line as a guide.
 - (b4) Secure Velcro strips at base of the patient's head. Leave 1 cm slack in the strips.
 - (b5) Verify that tube is secure, that it does not move forward from patient's mouth or backward down into patient's throat. Ensure that there are no pressure areas on oral mucosa or occipital region of the head.
- Secures tape to face and ET tube. Tube should be at same depth at the lips. Check earlier assessment for verification of tube depth in centimetres.
 - Commercially available holders have a slit in the front of the holder designed to secure the ET tube.
 - Ensures that the ET tube remains at the correct depth as determined during assessment.
 - The ET tube needs to be secure so that the position of the tube remains at the correct depth.
 - The tube must be secure so that the position of the tube remains at the correct depth. The tube can be secured without being tight and causing pressure.
 - Promotes hygiene. Reduces transmission of microorganisms.
- (16) Clean oral airway in warm, soapy water and rinse well. A half hydrogen peroxide and half normal saline solution aids in removal of crusted secretions. A mouthwash rinse will freshen patient's mouth. Shake excess water from oral airway. Be sure to rinse hydrogen peroxide mixture from airway.
- (17) For unconscious patient, reinsert oral airway without pushing tongue into oropharynx.

B. Tracheostomy care

- (1) Observe for signs and symptoms of need to perform tracheostomy care:
 - (a) Soiled or loose ties or dressing
 - (b) Nonstable tube
 - (c) Excessive secretions
 - (2) Suction tracheostomy (see Skill 38-1). Before removing gloves, remove soiled tracheostomy dressing and discard in glove with coiled catheter.
 - (3) Prepare equipment:
 - (a) Open sterile tracheostomy kit. Open two 4 × 4 inch gauze packages using aseptic technique, and pour normal saline (NS) on one package. Leave the second package dry. Open two packages of cotton-tipped swabs and pour NS on one package. Do not recap NS.
- Prevents patient from biting ET tube and allows access for oropharyngeal suctioning. An oral airway in a conscious, cooperative patient may cause excessive gagging and pressure ulcers to the mouth and tongue.
 - A patient with a tracheostomy tube is at increased risk because of loss of natural airway protection of the upper airway.
 - Removes secretions so as not to occlude outer cannula while inner cannula is removed. Reduces need for patient to cough. Prevents aspiration of retained secretions.
 - Disposal method helps to contain microorganisms.
 - Preparation and organization of equipment allows for efficient tracheostomy care and reconnecting of the patient to an oxygen source in a timely manner.

► SKILL 38-2 Care of an Artificial Airway—cont'd

- (b) Open sterile tracheostomy dressing package.
 - (c) Unwrap sterile basin and pour approximately 0.5–2 cm of normal saline into it.
 - (d) Open small sterile brush package and place aseptically into sterile basin.
 - (e) Prepare length of twill tape long enough to go around patient's neck two times, approximately 60–75 cm for an adult. Cut ends on diagonal. Lay aside in dry area.
 - (f) If using commercially available tracheostomy tube holder, open package according to manufacturer's directions.
 - (4) Apply sterile gloves. Keep dominant hand sterile throughout procedure.
 - (5) Hyperoxygenate the patient, if the patient has oxygen saturation levels below 92% (Demir & Dramali, 2005). Apply oxygen source loosely over tracheostomy if patient desaturates during procedure.
- Cutting ends of tie on diagonal aids in inserting tie through eyelet.
 - Reduces transmission of microorganisms.
 - Helps reduce amount of desaturation.

Critical Decision Point: For tracheostomy tube with no inner cannula or Kistner button, continue with Step B(8).

- (6) If a nondisposable inner cannula is used:
 - (a) While touching only the outer aspect of the tube, unlock and remove inner cannula with nondominant hand. Drop inner cannula into normal saline basin.
 - (b) Place tracheostomy collar or T tube and ventilator oxygen source over or near outer cannula. (Note: T tube and ventilator oxygen devices cannot be attached to all outer cannulas when inner cannula is removed.)
 - (c) To prevent oxygen desaturation in affected patients, quickly pick up inner cannula and use small brush to remove secretions inside and outside cannula (see Step 6B[6][c] illustration).
 - (d) Hold inner cannula over basin and rinse with NS, using nondominant hand to pour NS.
 - (e) Replace inner cannula and secure "locking" mechanism (see Step 6B[6][e] illustration). Reapply ventilator or oxygen sources.
- Removes inner cannula for cleaning. Normal saline loosens secretions from inner cannula.
 - Maintains supply of oxygen to patient.
 - Tracheostomy brush provides mechanical force to remove thick or dried secretions.
 - Removes secretions from inner cannula.
 - Secures inner cannula and re-establishes oxygen supply.

Step 6B(6)(c) Cleaning the tracheostomy inner cannula.

Step 6B(6)(e) Reinserting the inner cannula.

- (7) If a disposable inner cannula is used:
 - (a) Remove cannula from manufacturer's packaging.
 - (b) While touching only the outer aspect of the tube, withdraw inner cannula and replace with new cannula. Lock into position.
 - (c) Dispose of contaminated cannula in appropriate receptacle and apply oxygen source.
- Prevents unnecessary oxygen desaturation.

Continued

► SKILL 38-2 Care of an Artificial Airway—cont'd

video

- (8) Using normal saline saturated cotton-tipped swabs and 4 × 4 gauze, clean exposed outer cannula surfaces and stoma under faceplate, extending 5–10 cm in all directions from stoma (see Step 6B[8] illustration). Clean in circular motion from stoma site outward, using dominant hand to handle sterile supplies.

Step 6B(8) Cleansing around stoma.

- (9) Using dry 4 × 4 gauze, pat lightly at skin and exposed outer cannula surfaces.
- (10) Secure tracheostomy.
- (a) *Tracheostomy tie method:*
- (a1) Instruct assistant, if available, to apply gloves and securely hold tracheostomy tube securely in place while ties are cut.

- Aseptically removes secretions from stoma site. Moving in outward circle pulls mucus and other contaminants from stoma to periphery.

- Dry surfaces prevent formation of moist environment conducive to growth of microorganisms and prevent skin excoriation.

- Promotes hygiene, reduces transmission of microorganisms, and secures tracheostomy tube.

Critical Decision Point: Assistant must not release hold on tracheostomy tube until new ties are firmly tied to reduce risk of accidental extubation. If no assistant is present, do not cut old ties until new ties are in place and securely tied (Roman, 2005; St. John & Malen, 2004).

- (a2) Take prepared tie and insert one end of tie through faceplate eyelet, and pull ends even (see Step 6B[10][a2] illustration).

Critical Decision Point: Tracheostomy obturator should be kept at bedside with a fresh tracheostomy to facilitate reinsertion of the outer cannula, if dislodged. An additional tracheostomy tube of the same size and kind should be kept on hand for emergency replacement (Roman 2005; St. John & Malen, 2004).

- (a3) Slide both ends of tie behind head and around neck to other eyelet, and insert one tie through second eyelet.
- (a4) Pull snugly.
- (a5) Tie ends securely in double square knot, allowing space for only one loose or two snug finger widths in tie.
- (a6) Insert fresh tracheostomy dressing under clean ties and faceplate (see Step 6B[11][a6] illustration).

- Secures tracheostomy tube in place.
- One-finger slack prevents ties from being too tight when tracheostomy dressing is in place and prevents movement of tracheostomy tube into lower airway.
- Absorbs drainage. Dressing prevents pressure on clavicle heads.

Step 6B(10)(a2) Replacing tracheostomy ties when an assistant is not available. Do not remove old tracheostomy ties until new ones are secure.

Step 6B(10)(a6) Applying tracheostomy dressing.

SKILL 38-2 Care of an Artificial Airway—cont'd

video

(b) *Tracheostomy tube holder method:*

- (b1) While wearing gloves, maintain secure hold on tracheostomy tube. This can be done with an assistant, or, when an assistant is not available, by leaving the old tracheostomy tube holder in place until new device is secure.
- (b2) Align strap under patient's neck. Ensure that Velcro attachments are positioned on either side of tracheostomy tube.
- (b3) Place narrow end of ties under and through faceplate eyelets. Pull ends even, and secure with Velcro closures.
- (b4) Verify that there is space for only one loose or two snug finger width(s) under neck strap.

7. Position patient comfortably and assess respiratory status.

8. Replace any oxygen delivery devices.

9. Remove and discard gloves and face shield. Replace cap on normal saline. Perform hand hygiene.

10. Compare respiratory assessments before and after procedure.

11. Observe depth and position of tubes.

12. Assess security of tape or commercial ET or tracheostomy tube holder by tugging at tube.

13. Assess skin around mouth and oral mucosa (ET tube) and tracheostomy stoma for drainage, pressure, and signs of irritation.

- Prevents accidental displacement of tube.

- Promotes comfort. Some patients may require post-tracheostomy care suctioning.
- Maintains oxygen therapy.
- Reduces transmission of infection. Once opened, NS can be considered free of bacteria for 24 hours, after which it should be discarded.
- Identifies any changes in presence and quality of breath sounds after procedure.
- Verifies that position of tube is correct.
- Artificial airway should not move. Patient may cough.
- Skin breakdown or irritation should not be present.

Unexpected Outcomes*Accidental extubation**Breath sounds not equal bilaterally with ET tube in place**Hard, reddened areas with or without excessive or foul-smelling secretions**Insecure tube, artificial airway moves in or out, coughed out by patient**Breakdown, pressure areas, or stomatitis (tracheostomy tube)***Related Interventions**

- Call for assistance.
- Maintain patent airway. Replace old tracheostomy tube with new tube.
- Observe vital signs and signs of respiratory distress.
- Evaluate ET tube for proper depth. If incorrect, arrange for ET tube to be repositioned as allowed by institution.
- Obtain order for chest X-ray study to verify placement, if applicable.
- This indicates infection. Notify physician.
- Increase frequency of tube care.
- Remove inner cannula, if applicable, for cleaning and suctioning.
- Assess patient's respiratory status and observe for the presence of mucus plugs.
- Adjust or apply new ties.
- Increase frequency of tube care.
- Make sure skin areas are clean and dry.

Recording and Reporting

- Record respiratory assessments before and after care.
- Record ET tube care: depth of ET tube, frequency and extent of care, patient tolerance, and any complications related to presence of the tube.
- Record tracheostomy care: type and size of tracheostomy tube, frequency and extent of care, patient tolerance, and any complications related to presence of the tube.

Home Care Considerations (Tracheostomy Only)

- Instruct caregivers on how to obtain supplies.
- Instruct caregivers on signs and symptoms of respiratory distress, tube dysfunction, and respiratory and stoma infections.

position are simple and cost-effective methods for reducing the risks of stasis of pulmonary secretions and decreased chest wall expansion.

The most effective position for patients with cardiopulmonary diseases is the 45-degree semi-Fowler's position, using gravity to assist in lung expansion and reduce pressure from the abdomen on the diaphragm. When the patient uses this position, ensure that the patient does not slide down in bed, which could reduce lung expansion. A patient with unilateral lung disease (e.g., pneumothorax, atelectasis, pneumonia, thoracotomy, multiple trauma affecting one lung) should be positioned with the unaffected lung down ("good lung down"). This promotes better perfusion of the healthy lung, improving oxygenation. In the presence of pulmonary abscess or hemorrhage, the patient should be placed with the affected lung down to prevent drainage toward the unaffected (healthy) lung.

Incentive Spirometry. Incentive spirometry is a method of encouraging voluntary deep breathing by providing visual feedback to patients about inspiratory volume. Incentive spirometry is used to promote deep breathing and to prevent or treat atelectasis in the postoperative patient. The use of an incentive spirometer to promote lung expansion and thus prevent postoperative pulmonary complications following abdominal surgery is supported by research (Lawrence et al., 2006).

Flow-oriented incentive spirometers consist of one or more plastic chambers containing freely moving coloured balls. The patient inhales slowly and with an even flow to elevate the balls and keep them floating as long as possible to ensure a maximally sustained inhalation.

Volume-oriented incentive spirometry devices have a bellows that is raised to a predetermined volume by an inhaled breath (Figure 38-13). An achievement light or counter is used to provide feedback. Some devices are constructed so that the light will not turn on unless the bellows is held at a minimum desired volume for a specified period to enhance lung expansion.

The aim of incentive spirometry is to encourage patients to breathe to their normal inspiratory capacities. A postoperative inspiratory capacity one-half to three-fourths of the

Figure 38-13 Volume-oriented spirometer.

preoperative volume is acceptable because of postoperative pain. Administration of pain medications before incentive spirometry will help the patient achieve deep breathing by reducing pain and splinting (see Chapter 48).

Chest Tubes. Chest tubes are inserted to remove air and fluids from the pleural space, prevent air or fluid from re-entering the pleural space, and re-establish normal intrapleural and intrapulmonic pressures. A **chest tube** is a catheter inserted through the thorax to remove fluid or air. There are a variety of chest drainage systems on the market. In addition to the usual disposable waterless system, the traditional reusable-glass, three-bottle systems may still be used. One of the newest systems available is the mobile chest drain.

Mobile systems rely on gravity, not suction, for drainage. In specific patients, these mobile drains reduce the length of time needed for the chest tube, improve ambulation, and decrease the length of time in the hospital (Carroll, 2005). Mobile chest drains are lighter and smaller, thus the patient is able to move more easily (Carroll, 2005).

Chest tubes are commonly used after chest surgery and chest trauma and for pneumothorax or hemothorax to promote lung re-expansion (Skill 38-3).

A **pneumothorax** is a collection of air in the pleural space. The loss of negative intrapleural pressure causes the lung to collapse. There are a variety of mechanisms for a pneumothorax. It may occur spontaneously or as a result of chest trauma, such as a stabbing or the chest striking the steering wheel in a motor vehicle accident. A pneumothorax may also result from the rupture of an emphysematous bleb on the surface of the lung (a large bulla resulting from the destruction caused by emphysema) or from an invasive procedure, such as insertion of a subclavian IV line.

A patient with a pneumothorax usually feels pain as atmospheric air irritates the parietal pleura. The pain may be sharp and pleuritic. Dyspnea is common and worsens as the size of the pneumothorax increases.

A **hemothorax** is an accumulation of blood and fluid in the pleural cavity between the parietal and visceral pleurae, usually as a result of trauma. It produces a counterpressure and prevents the lung from full expansion. A hemothorax can also be caused by the rupture of small blood vessels from inflammatory processes, such as pneumonia or TB. In addition to pain and dyspnea, signs and symptoms of shock can develop if blood loss is severe.

Disposable systems, such as an Atrium or Pleur-Evac chest drainage system, are one-piece molded plastic units that provide for a single- or multiple-chamber closed drainage system (Figure 38-14). A single chamber system allows air from a pneumothorax to bubble out of the water seal and escape through the air outlet, preventing air from re-entering the intrapleural space (Perry, 2010, p. 702). A two- or three-chamber system drains both a hemothorax and a pneumothorax. The two-chamber system allows fluid to flow into a collection chamber and air flows into the water seal chamber (Perry, 2010, p. 702). A three-chamber system permits the drainage of fluid and air using controlled suction (Perry, 2010, p. 702). The two- and three-chamber systems have two compartments, one for fluid or blood and a second for a water seal or a one-way valve (Perry, 2010, p. 702). The three-chamber system has a third compartment for suction control which may or may not be used (Perry, 2010, p. 702).

There are two types of commercial drainage devices: water-seal and waterless systems. Although the principles of the

► SKILL 38-3 Care of Patients With Chest Tubes

Delegation Considerations

This skill should not be delegated to nursing assistive personnel (NAP). However, a NAP may assist with other aspects of the patient's care. It is important to inform the NAP of the following:

- Proper positioning of the patient with chest tubes to facilitate chest tube drainage and optimal function of the system
- How to ambulate and transfer a patient with chest drainage
- To report to the nurse any changes in vital signs, chest pain, sudden shortness of breath, or excessive bubbling in the water-seal chamber
- To immediately report to the nurse a disconnection of the system, any change in type and amount of drainage, sudden bleeding, or sudden cessation of bubbling.

Procedure

STEPS

1. Perform hand hygiene and assess patient.
 - A. Pulmonary status: Assess for respiratory distress, chest pain, breath sounds over affected lung area, and stable vital signs (see Chapter 30). Signs and symptoms of increased respiratory distress or chest pain include decreased breath sounds over the affected and nonaffected lungs, marked cyanosis, asymmetrical chest movements, presence of **subcutaneous emphysema** (air trapped in the subcutaneous tissue) around tube insertion site or neck, hypotension, and tachycardia (Carroll, 2002).
 - B. Vital signs, SpO₂, and level of orientation.
 - C. Pain: If possible, ask patient to rate level of pain on a scale of 0 to 10.
2. Observe:
 - A. Chest tube dressing and site surrounding tube insertion.
 - B. Tubing for kinks, dependent loops, or clots.
 - C. Chest drainage system, which should be upright and below level of tube insertion.
3. Provide two shodded hemostats or approved clamps for each chest tube, attached to the top of patient's bed with adhesive tape. Chest tubes are clamped only under specific circumstances per physician order or nursing policy and procedure:
 - A. To assess air leak.
 - B. To quickly empty or change disposable systems; performed by a nurse who has received education in the procedure.
 - C. To assess if patient is ready to have the chest tube removed (which is done by physician's order); monitor the patient for recurrent pneumothorax (Roman & Mercado, 2006).
4. Position patient.
 - A. Semi-Fowler's to high-Fowler's position to evacuate air (pneumothorax).
 - B. High-Fowler's position to drain fluid (hemothorax, effusion).
5. Maintain tube connection between chest and drainage tubes; ensure that it is intact and secured with waterproof adhesive tape. Check patency of air vents in system:

Equipment

- Disposable chest drainage system (see Figure 38-14)
- Suction source and set-up (wall canister or portable)
- Disposable (nonsterile) gloves
- 5 cm tape
- Sterile gauze sponges
- Two shodded hemostats

RATIONALE

- Signs and symptoms should reflect improvement in respiratory distress and chest pain after insertion of chest tube.
- Notify physician immediately.
- Changes in pulse and blood pressure may indicate infection, respiratory distress, or pain.
- Chest tubes can be painful and interfere with a patient's mobility, coughing and deep breathing, and rehabilitation.
- Ensures that dressing is intact and occlusive seal remains without air or fluid leaks and that area surrounding insertion site is free of drainage or skin irritation (Carroll, 2002).
- Maintains a patent, freely draining system, preventing fluid accumulation in the chest cavity. Presence of kinks, dependent loops, or clotted drainage increases the risk for infection, atelectasis, and tension pneumothorax (Allibone, 2003).
- Facilitates drainage; the system must be in this position to function properly.
- Shodded hemostats have a covering to prevent hemostat from penetrating the chest tube once changed. The use of these shodded hemostats or other clamp prevents air from re-entering the pleural space (Allibone, 2003).
- Permits optimal drainage of fluid and air.
- Air rises to the highest point in the chest. Pneumothorax tubes are usually placed on the anterior aspect at the midclavicular line, second or third intercostal space (Allibone, 2003).
- Permits optimal drainage of fluid. Posterior tubes are placed on the midaxillary line, fifth or sixth intercostal space.
- Secures chest tube to drainage system and reduces risk of air leak causing breaks in airtight system.

Continued

► SKILL 38-3 Care of Patients With Chest Tubes—cont'd

- A. Water-sealed vent must be without occlusion.
- B. Suction-control chamber vent must be without occlusion when suction is used.
- C. Confirm that valves are unobstructed. Waterless systems have relief valves without caps. For dry suction systems, the positive pressure relief valve must remain unobstructed.
- 6. Avoid excess tubing; the tubing should be laid horizontally across the patient bed or chair before dropping vertically into the drainage bottle. If the patient is in a chair and the tubing is coiled, the tubing should be lifted every 15 minutes to promote drainage.
- 7. Adjust tubing to hang in a straight line from top of mattress to drainage chamber. If chest tube is draining fluid, indicate time (e.g., 0900) that drainage was begun on drainage bottle's adhesive tape or on write-on surface of disposable commercial system.
- Permits displaced air to pass into atmosphere.
- Provides safety factor of releasing excess negative pressure into the atmosphere. Too little suction prevents lung re-expansion and increases patient risk for infection, atelectasis, and tension pneumothorax. Too much suction damages the lung tissue and perpetuates existing air leaks (Allibone, 2003).
- Provides safety factor of releasing excess negative pressure.
- The length of tubing should be tailored to each patient to avoid excessive coiling or loop formation. Fluid collection in the loop may occlude system thus predisposing patient to a tension pneumothorax (Roman & Mercado, 2006).
- Provides a baseline for continuous assessment of type and quality of drainage.

Critical Decision Point: Frequent gentle lifting of sections of the drain allows gravity to assist blood and other viscous material to move to the drainage bottle. Patients with recent chest surgery or trauma need to have the chest drain lifted based on the amount of drainage; some patients may require the chest drain lifted every 5-10 minutes until the volume decreases (Lehwaldt & Timmins, 2005).

Critical Decision Point: Check institutional policy before stripping or milking chest tubes. This practice is being discontinued at most institutions because it is believed that stripping the tube greatly increases intrathoracic pressure, which damages the pleural tissue and causes or worsens an existing pneumothorax. Although the literature is contradictory, milking may be done in selected patients (e.g., fresh postoperative thoracic surgery in presence of multiple clots). The rationale for this selective use of stripping or milking is that the presence of clotted tube drainage causes decreased rate of re-expansion and increases the risk for a tension pneumothorax (Allibone, 2003).

- 8. Perform hand hygiene.
- 9. Evaluate:
 - A. Vital signs and pulse oximetry as ordered or if patient's condition changes.
 - B. Chest tube dressing.
 - Reduces transmission of infection.
 - Provides ongoing data about the patient's level of oxygenation.
 - Appearance of drainage may be due to tube occlusion, causing drainage to exit around tube.

Critical Decision Point: Check the dressing carefully because it must remain occlusive. It can come loose from the skin, although this may not be readily apparent.

- C. Tubing: It should be free of kinks and dependent loops.
- D. Chest drainage system: It should be upright and below level of tube insertion. Note presence of clots or debris in tubing.
- E. Water seal for fluctuations with patient's inspiration and expiration.
 - (1) Waterless system: Diagnostic indicator for fluctuations for patient's inspirations and expirations.
 - (2) Water-seal system: Bubbling in the water-seal chamber.
 - (3) Water-seal system: Bubbling in the suction-control chamber (when using suction).
 - Straight and coiled drainage tube positions are optimal for pleural drainage. However, when a dependent loop is unavoidable, periodic lifting and drainage of the tube will promote pleural drainage (Allibone, 2003; Lehwaldt & Timmins, 2005).
 - The system must be in the upright position to function and facilitate proper drainage.
 - In a nonmechanically ventilated patient, fluid should rise in the water seal or diagnostic indicator with inspiration and fall with expiration. The opposite occurs in a patient who is mechanically ventilated. This indicates the system is properly functioning.
 - When system is initially connected to patient, bubbles are expected from the chamber. These are from air that was present in the system and in the patient's intrapleural space. After a short time, the bubbling stops. Fluid will continue to fluctuate in the water seal on inspiration and expiration until the lung is re-expanded or the system becomes occluded.
 - The suction-control chamber has constant gentle bubbling. Tubing remains free of obstruction and the suction source is turned to the appropriate setting.

► SKILL 38-3 Care of Patients With Chest Tubes—cont'd

- F. Waterless system: Bubbling in diagnostic indicator.
- G. Waterless system: The suction control (float ball) indicates the amount of suction that the patient's intrapleural space is receiving.
- H. Type and amount of fluid drainage: Note colour and amount of drainage, patient's vital signs, and skin colour. Assess the fluid in the collection tubing, not just the drainage in the collection chamber. The normal amount of drainage is as follows:
 - (1) In the adult: <50–200 mL/hour immediately after surgery in a mediastinal chest tube; approximately 500 mL in first 24 hours.
 - (2) In the adult: Between 100 and 300 mL of fluid may drain in a pleural chest tube in an adult during the first three hours after insertion. The 24-hour rate is 500–1000 mL. Drainage is grossly bloody during the first several hours after surgery and then changes to serous. Remember that a sudden gush of drainage may be retained blood and not active bleeding. This increase in drainage can result from patient position changes.
- Mechanism to observe for the presence of tidalling.
- The suction float ball dictates the amount of suction in the system. The float ball allows no more suction than allowed by its setting. If the suction source is set too low, the suction float ball cannot reach the prescribed setting. In this case, the suction must be increased for the float ball to reach the prescribed setting.
- A **mediastinal chest tube** is commonly used following open heart surgery. It is inserted in the mediastinum (below the sternum) and is connected to a drainage system. This tube drains blood or fluid thus preventing accumulation around the heart. Dark-red drainage is expected only in the postoperative period, turning serous with time.
- Re-expansion of lungs forces drainage into the tube. Coughing can also cause large gushes of drainage or air. Acute bleeding indicates hemorrhage.

Critical Decision Point: Inform the physician, remain with the patient, and assess vital signs and cardiopulmonary status if drainage suddenly increases, is bright red, or if there is >100 mL/hour of bloody drainage (except for the first three hours postoperative).

- I. Observe patient for decreased respiratory distress and chest pain, auscultate lung sounds over affected area, and monitor SpO₂.
 - An increase in respiratory distress and/or chest pain, decrease in breath sounds over affected and unaffected lungs, cyanosis, asymmetrical chest movements, subcutaneous emphysema around the insertion site or neck, hypotension, tachycardia, and/or a mediastinal shift are critical and indicate a change in patient status (e.g., excessive blood loss, tension pneumothorax) (Allibone, 2003). This must be reported immediately to the patient's health care provider.
 - May indicate the need for medication for pain.
- J. Pain: Ask patient to evaluate pain on a level of 0 to 10.

Unexpected Outcomes

Continuous bubbling in water-sealed chamber

Related Interventions

- This indicates a leak between the patient and water seal.
- Assess all connections between the patient and drainage system, and tighten any loose connections (Cerfolio, 2005).
- Check institution policy, and if instructed, cross-clamp chest tube close to patient's chest. If bubbling stops, air leak is inside patient's thorax or at chest tube insertion site. Unclamp tube, and notify physician immediately. Reinforce chest dressing. Leaving a chest tube clamped causes a tension pneumothorax and mediastinal shift.
- Gradually move clamps down drainage tubing away from the patient and toward the suction control chamber, moving one clamp at a time. When bubbling stops, the leak is in a section of tubing or connection between clamps. Replace tubing or secure connection and release clamp.

Continued

► SKILL 38-3 Care of Patients With Chest Tubes—cont'd

Chest tube is dislodged

Tension pneumothorax

Substantial increase in bright red drainage

No chest tube drainage

- Immediately apply pressure over chest tube insertion site.
- Have assistant apply occlusive gauze dressing and tape three sides.
- Notify physician.
- Determine that chest tubes are not clamped, kinked, or occluded. Obstructed chest tubes trap air in the intrapleural space when an air leak originates within the patient.
- Notify physician immediately.
- Prepare immediately for another chest tube insertion; obtain a flutter (Heimlich) valve or large-gauge needle for short-term emergency release of air in the intrapleural space. Have emergency equipment (e.g., oxygen, code cart) near patient.
- Obtain vital signs and monitor drainage.
- Assess patient's cardiopulmonary status and notify physician.
- Observe for kink and possible clot in the chest drainage system.
- Assess for mediastinal shift or respiratory distress (medical emergency) and notify physician.

Recording and Reporting

- Record in nurse's notes patency of chest; presence, type, and amount of drainage; presence of fluctuations; patient's vital signs; chest dressing status, amount of suction and water seal; and level of comfort.

Home Care Considerations

- Patients with chronic conditions (e.g., uncomplicated pneumothorax, effusions, empyema) that require a chest tube may be discharged home with smaller mobile chest drains. These systems do not have a suction-control chamber and use a mechanical one-way valve instead of a water-seal chamber (Carroll, 2002, 2005).
- Instruct patient in how to ambulate and remain active with a home chest tube drainage system.
- Provide patient with information on when to contact health care providers regarding changes in drainage system (e.g., chest pain, breathlessness, change in drainage).

Figure 38-14 Dry suction chest drainage system. **Source:** Courtesy Atrium Medical Corp. From Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills & techniques* (7th ed., p. 705, Fig 26-8). St Louis, MO: Mosby.

waterless are similar to those of the water-seal system, there are structural differences. The waterless system does not require fluid for setup and the water seal is replaced by a one-way valve (Perry, 2010, p. 703). The suction chamber, which does not depend on water, contains a float ball that is set by a control dial after the suction source is initiated (Perry, 2010, p. 703). Dry suction chest drainage systems (Figure 38-14) provide higher suction pressure levels. A self-compensating regulator controls dry suction units, and a dial is set to the prescribed suction control setting (Perry, 2010, p. 704). Pressure is set between -10 cm H_2O and -40 cm H_2O .

Special Considerations. Clamping a chest tube at any time is inadvisable. Handle the chest drainage unit carefully and maintain the drainage device below the patient's chest. If the tubing disconnects from the drainage unit, instruct the patient to exhale as much as possible and to cough. This manoeuvre rids the pleural space of as much air as possible. Cleanse the tips of the tubing and reconnect them quickly. If the drainage unit is broken, the end of the chest tube can be quickly submerged in a container of sterile water to re-establish the seal. Clamping the chest tube may result in a tension pneumothorax. Air pressure builds in the pleural space, collapsing the lung and creating a life-threatening event.

Removal of chest tubes requires patient preparation. Patients report various sensations during chest tube removal. The most frequent sensations include burning, pain, and a pulling sensation.

Maintenance and Promotion of Oxygenation. Promotion of lung expansion and of mobilizing secretions and maintaining a patent airway assists the patient in meeting

oxygenation needs. Some patients, however, also require oxygen therapy to keep a healthy level of tissue oxygenation.

Oxygen Therapy. Oxygen therapy is widely available and used in a variety of settings to relieve or prevent tissue hypoxia (Gardner & Wilkins, 2009, p. 1256). The goal of oxygen therapy is to prevent or relieve hypoxia. Any patient with impaired tissue oxygenation can benefit from controlled oxygen administration. Oxygen is not a substitute for other treatment, however, and should be used only when indicated. Oxygen should be treated as a drug. It has dangerous side effects, such as atelectasis or oxygen toxicity (Heuer & Scanlan, 2009, p. 870). As with any drug, the dosage or concentration of oxygen should be continuously monitored. Routinely check the physician's orders to verify that the patient is receiving the prescribed oxygen concentration. The seven rights of medication administration also pertain to oxygen administration (see Chapter 33).

Safety Precautions. Oxygen is a highly combustible gas. Although it will not spontaneously burn or cause an explosion, it can easily cause a fire to ignite in a patient's room if it contacts a spark from an open flame or electrical equipment. With increasing use of home oxygen therapy, patients and health care providers must be aware of the dangers of combustion.

safety alert Oxygen in high concentrations has a great combustion potential and readily fuels fire.

Promote oxygen safety by using the following measures:

- Inform the patient, visitors, roommates, and all personnel that smoking is not permitted in areas where oxygen is in use.
- Ensure that all electrical equipment in the room is functioning correctly and is properly grounded (see Chapter 36). An electrical spark in the presence of oxygen can result in a serious fire.
- Locate the closest fire extinguisher.
- Know the fire procedures and the evacuation route for the area.
- Check the oxygen level of portable tanks before transporting a patient to ensure that enough oxygen in the tank exists to complete the transport.

Supply of Oxygen. Oxygen is supplied to the patient's bedside either by oxygen tanks or through a permanent wall-piped system. Oxygen tanks are transported on wide-based

carriers that allow the tank to be placed upright at the bedside. Regulators are used to control the amount of oxygen delivered. One common type is an upright flowmeter with a flow adjustment valve at the top. A second type is a cylinder indicator with a flow adjustment handle. In the home setting, oxygen therapy is also supplied in a variety of methods, including refillable cylinders (Cuvelier et al., 2002).

In the hospital or home, oxygen tanks are delivered with the regulator in place. In the hospital, the respiratory care department usually connects the regulator to the oxygen source. Home care vendors are usually responsible for connecting the oxygen tank to the regulator for home use.

Methods of Oxygen Delivery. Oxygen delivery devices can be considered low-flow or high-flow systems. **Low-flow devices** such as nasal cannulas, simple face masks, and reservoir masks provide oxygen in concentrations that vary with the patient's respiratory pattern (Heuer & Scanlan, 2009, p. 874; Kratochvil, 2005, p. 611). **High-flow devices** deliver oxygen rates above the normal inspiratory flow rate and thus provide a fixed FiO_2 (fraction of inspired oxygen) regardless of the patient's inspiratory flow and breathing pattern (Heuer & Scanlan, 2009, p. 873). The Venturi mask is an example of a high-flow device (Kratochvil, 2005, p. 611).

Nasal Cannula. A nasal cannula is a low-flow device used for oxygen delivery (Skill 38-4). The two cannulas, approximately 1.5 cm long, protrude from the centre of a disposable tube and are inserted into the nares (Figure 38-15). Oxygen is

Figure 38-15 Nasal cannula.

► SKILL 38-4 Applying a Nasal Cannula or Oxygen Mask

video

Delegation Considerations

This skill cannot be delegated to nursing assistive personnel (NAP). You are responsible for assessing the patient and providing safe and accurate oxygen therapy, including adjustment of oxygen flow rate and evaluation of patient response. It is important to instruct the NAP about the following:

- Correct placement and adjustment of delivery device
- The type of equipment and the oxygen flow rate
- Unexpected outcomes associated with the oxygen delivery device (e.g., increased rate of breathing, decreased level of consciousness, increased confusion, pain, changes in vital signs) and the need to inform you if any of these outcomes occur

Equipment

- Oxygen delivery device (e.g., nasal cannula or oxygen mask)
- Oxygen tubing
- Humidifier, if indicated
- Sterile water for humidification, if indicated
- Oxygen source
- Oxygen flowmeter
- Appropriate room signs

Continued

► SKILL 38-4 Applying a Nasal Cannula or Oxygen Mask—cont'd

video

Procedure

STEPS

1. Inspect patient for signs and symptoms associated with hypoxia and presence of airway secretions.

Critical Decision Point: Patients with sudden changes in their vital signs, level of consciousness, or behaviour may be experiencing profound hypoxia. Patients who demonstrate subtle changes over time may have worsening of a chronic or existing condition or have a new medical condition (Jarvis, 2006).

2. Obtain patient's most recent SpO₂ or arterial blood gas (ABG) values. Review patient's medical record for the medical order for oxygen, noting delivery method, flow rate, and duration of oxygen therapy.
3. Explain to the patient and family what the procedure entails and the purpose of oxygen therapy.
4. Perform hand hygiene.
5. Attach oxygen delivery device (e.g., nasal cannula, mask) to oxygen tubing and attach to humidified oxygen source adjusted to prescribed flow rate (see Step 5 illustration).
6. Place tips of cannula into patient's nares, and adjust elastic headband or plastic slide until cannula or face mask fits snugly and comfortably (see Step 6 illustration).

RATIONALE

- Left untreated, hypoxia can produce cardiac dysrhythmias and death. Presence of airway secretions decreases the effectiveness of oxygen delivery.
- Provides objective baseline data to use to compare outcome of oxygen therapy. Ensures safe and accurate oxygen administration.
- Decreases patient's anxiety, which reduces oxygen consumption and increases patient cooperation.
- Reduces transmission of infection.
- Humidity prevents drying of nasal and oral mucous membranes and airway secretions. Ensures correct oxygen delivery.
- Directs flow of oxygen into patient's upper respiratory tract. Patient is more likely to keep device in place if it fits comfortably.

Step 5 Adjusting flowmeter to prescribed oxygen flow rate.

7. Maintain sufficient slack on oxygen tubing and secure to patient's clothes.
8. Observe for proper function of oxygen delivery device:

(a) Nasal cannula: Cannula is positioned properly in the nares.

(b) Nonrebreathing mask: Apply mask over patient's mouth and nose to form a tight seal. The valves on the mask close, so exhaled air does not enter reservoir bag.

Step 6 Adjusting nasal cannula to fit patient and ensure comfort.

- Allows patient to turn head without dislodging nasal cannula or causing mask to shift position.
- Ensures patency of delivery device and accuracy of prescribed oxygen flow rate.
- Provides prescribed oxygen rate and reduces pressure on tips of nares.
- Does not allow exhaled air to be rebreathed. Valves on mask side ports permit exhalation but close during inhalation to prevent inhaling room air.

SKILL 38-4 Applying a Nasal Cannula or Oxygen Mask—cont'd

video

- (c) Partial rebreathing mask: Apply mask over patient's mouth and nose to form a tight seal. Ensure that the bag remains partially inflated.
- (d) Venturi mask: Apply mask over patient's mouth and nose to form a tight seal. Select appropriate flow rate.
- 9. Check cannula/mask every eight hours. Keep humidification container filled at all times.
- 10. Observe patient's nares and superior surface of both ears for skin breakdown.
- 11. Perform hand hygiene.
- 12. Verify oxygen flow rate, proper set-up, and physician's orders.
- 13. Inspect patient for relief of symptoms associated with hypoxia.
- Allows exhaled air to mix with inhaled air. Ports on the side of the mask permit most of the expired air to escape; however the bag remains partially inflated.
- Reduces buildup of carbon dioxide.
- Ensures patency of cannula/mask and oxygen flow. Prevents inhalation of dehumidified oxygen.
- Oxygen therapy can cause drying of nasal mucosa. Pressure on ears from cannula tubing or elastic can cause skin irritation.
- Reduces transmission of microorganisms.
- Ensures delivery of prescribed oxygen flow rate and patency of cannula/mask.
- Indicates that hypoxia is corrected or reduced.

Unexpected Outcomes*Worsening respiratory status**Dry nasal and upper airway mucosa**Skin breakdown over ears***Related Interventions**

- Check that oxygen delivery device is patent, not kinked, and attached to the oxygen flowmeter.
- Check oxygen level set on flowmeter; determine if delivered amount is consistent with physician order.
- If not using wall oxygen, determine if the oxygen source contains enough oxygen to deliver the prescribed oxygen amount.
- Notify physician.
- If oxygen flow rate is >4 L/minute, determine the need for humidification.
- Assess the patient's fluid status and increase fluids if appropriate.
- Provide frequent oral care.
- Obtain physician order for use of sterile nasal saline intermittently.
- Adjust tightness of elastic strap to looser level.
- Use good hygiene and skin care around the ears.
- Place soft, woven 4×4 gauze pads between elastic and ears.
- Reposition elastic strap frequently.

Recording and Reporting

- Record oxygen delivery device and litre flow in medical record. Document patient and family education. Report oxygen delivery device, litre flow, and response to changes in therapy to oncoming shift.

TABLE 38-9 Approximate FiO_2 with Different Oxygen Delivery Devices

Oxygen Delivery Device	Required Litre Flow (L/minute)	Approximate Percent Oxygen
Nasal cannula	1–2	24–28
	3–4	32–36
	5–6	40–44
Simple face mask	5–6	40
	6–7	50
	7–8	60
Venturi mask	4	24–28
	8	35–40
	12	50–60

delivered via the cannulas with a flow rate of up to 6 L/minute. Flow rates greater than 4 L/minute are not often used because of the drying effect on the mucosa and the relatively little increase in delivered oxygen concentration. Know what flow rate produces a given percentage of inspired oxygen concentration (FiO_2 ; Table 38-9). Also be alert for skin breakdown over the ears and in the nares from too tight an application of the nasal cannula.

Oxygen Masks. An oxygen mask is a device used to administer oxygen, humidity, or heated humidity. It is shaped to fit snugly over the mouth and nose and is secured in place with a strap.

The simple face mask (Figure 38-16) is used for short-term oxygen therapy. It fits loosely and delivers oxygen concentrations from 40% to 60%. The mask is contraindicated for patients with carbon dioxide retention because retention can be worsened.

The partial rebreathing mask and the non-rebreathing mask are low-flow devices with a reservoir bag (Figure 38-17). The partial rebreather mask provides an oxygen concentration of 40% to 70% with a minimum flow rate of 10 L/minute (Heuer & Scanlan, 2009, p. 874). The non-rebreather provides a high concentration of oxygen at 60% to 80% with a minimum flow rate of 10 L/minute (Heuer & Scanlan, 2009, p. 874). Oxygen flows into the reservoir bag and mask during inhalation; one-way valves on the non-rebreather mask prevent expired air from flowing back into the bag. Frequently inspect the bag to make sure it is inflated. If it is deflated, the patient may be breathing large amounts of exhaled carbon dioxide.

The Venturi mask (Figure 38-18), a high-flow device, can be used to deliver oxygen concentrations of 24% to 60% with oxygen flow rates of 4 to 12 L/minute, depending on which flow-control meter is selected (see Table 38-9). This mask

Figure 38-16 Simple face mask.

Figure 38-17 Plastic face mask with reservoir bag.

Figure 38-18 Venturi mask.

entrains room air to achieve a consistent and precise oxygen concentration. The Venturi mask is helpful for patients with COPD who require low, constant oxygen concentrations.

Home Oxygen Therapy. Indications for home oxygen therapy include a PaO_2 of 55 mm Hg or less or an SaO_2 of 88% or less on room air at rest, on exertion, or with exercise. Patients with a PaO_2 from 56 to 59 mm Hg may receive oxygen if there is also evidence of cor pulmonale, pulmonary hypertension, erythrocytosis, central nervous system dysfunction, impaired mental status, or increasing hypoxemia with exertion.

Home oxygen therapy has a beneficial effect for patients with chronic cardiopulmonary diseases (Snow et al., 2001). This therapy improves patients' exercise tolerance and fatigue levels and in some situations assists in the management of dyspnea (Fujimoto et al., 2002). When home oxygen is required, it is usually delivered by nasal cannula. When a patient has a

permanent tracheostomy, however, a T tube or tracheostomy collar is necessary. Three types of oxygen are used: compressed oxygen, liquid oxygen (Figure 38-19), and oxygen concentrators. The advantages and disadvantages (Table 38-10) of each type are assessed, along with the patient's needs and community resources, before placing a certain delivery system in the home. In the home, the major consideration is the oxygen delivery source.

Patients requiring home oxygen need extensive teaching to be able to continue oxygen therapy at home efficiently and safely (Skill 38-5). This includes oxygen safety, regulation of the amount of oxygen, and how to use the prescribed home oxygen delivery system. It is important to coordinate the efforts of the patient and family, home care nurse, home respiratory therapist, and home oxygen equipment vendor. The social worker usually assists with arranging for the home care

nurse and oxygen vendor. Assist the patient and family in learning about home oxygen and ensure their ability to maintain the oxygen delivery system.

Restoration of Cardiopulmonary Functioning. If a patient's hypoxia is severe and prolonged, cardiac arrest may result. A cardiac arrest is a sudden cessation of cardiac output and circulation. When this occurs, oxygen is not delivered to tissues, carbon dioxide is not transported from tissues, tissue metabolism becomes anaerobic, and metabolic and respiratory acidosis occurs. Permanent heart, brain, and other tissue damage occurs within four to six minutes.

Cardiopulmonary Resuscitation. Cardiac arrest is characterized by an absence of pulse and respiration. If you determine that the patient has had a cardiac arrest, **cardiopulmonary**

resuscitation (CPR) must be initiated. CPR is a basic emergency procedure of artificial respiration and manual external cardiac massage. Most nursing students are required to have successfully completed a CPR course before their clinical experiences.

Figure 38-19 Primary and portable liquid oxygen source for ambulation.

TABLE 38-10 Home Oxygen Systems

Primary Use	Advantages	Disadvantages
Compressed Gas Cylinders		
Intermittent therapy	100% oxygen, relatively inexpensive, no loss of gas during storage, relatively portable, delivery of up to 15 L/minute	Bulky, possibly unsightly, frequent refilling necessary with continuous use
Used for exercise or sleep only		
Liquid Oxygen Systems (see Figure 38-19)		
Used with active patients	100% oxygen, conveniently portable, portable units refilled at home, delivery of up to 6 L/minute	Usually weekly delivery necessary for refill, evaporates if not used, potential for frostbite at connections and if liquid is spilled
Oxygen Concentrators		
Homebound patients with limited mobility inside or outside home	Fixed monthly cost, minimal interruption of household by supplier, no refills of "main tank," most units with delivery of up to 4 or 5 L/minute	Oxygen concentration decreases as litre flow increases (usually 85%–90%), power supply needed, electric bill increase, second system needed for portability, usually E tank gas cylinders

SKILL 38-5 Using Home Oxygen Equipment

Delegation Considerations

This skill should not be delegated to nursing assistive personnel (NAP). However, once the patient is stable on home oxygen therapy, NAP may perform certain aspects of care. You are responsible for assessing the patient, checking the device set-up, and providing safe and accurate oxygen therapy. You must instruct the NAP about the following:

- Unique needs of the patient (e.g., home nasal cannula or mask) and any assistance needed in filling liquid canisters
- The type of equipment that the patient should have in the home and the oxygen flow rate
- Unexpected outcomes associated with the oxygen delivery device (e.g., increased rate of breathing, decreased level of consciousness, increased confusion, pain), and the need to inform you if any occur

Equipment

- Nasal cannula, oxygen mask, or other prescribed delivery device (see Skill 38-4)
- Oxygen tubing
- Home oxygen delivery system with appropriate equipment
- "No Smoking/Oxygen in Use" sign for each entrance to home

Continued

► SKILL 38-5 Using Home Oxygen Equipment—cont'd

Procedure

STEPS

1. While patient is in the hospital, determine patient's or family's ability to use oxygen equipment correctly. In the home setting, reassess for appropriate use of equipment.
2. Assess home environment for adequate electrical service if oxygen concentrator is used.
3. Assess patient's and family's ability to observe for signs and symptoms of hypoxia.
4. Determine appropriate resources in the community for equipment and assistance, including maintenance and repair services, and medical equipment supplier.
5. In case of power failure, determine appropriate backup system when using a compressor. Have a spare oxygen tank available.
6. Perform hand hygiene.
7. Place oxygen delivery system in a clutter-free environment that is well ventilated; away from walls, drapes, bedding, combustible materials; and at least eight feet from heat source.
8. Demonstrate steps for preparation and completion of oxygen therapy.
 - A. Compressed oxygen system
 - (1) Turn cylinder valve counterclockwise two to three turns with wrench. Store wrench with oxygen tank.
 - (2) Check cylinders by reading amount on pressure gauge.
 - B. Oxygen concentrator system
 - (1) Plug concentrator into appropriate outlet.
 - (2) Turn on power switch.
 - (3) Alarm will sound for a few seconds.
 - C. Liquid oxygen system
 - (1) Check liquid system by depressing button at lower right corner and reading the dial on the stationary oxygen reservoir or ambulatory tank.
 - (2) Collaborate with medical equipment provider to receive instruction on refilling ambulatory tank.

RATIONALE

- Physical or cognitive impairments of patient necessitate instructing a family member or significant other how to operate home oxygen equipment. Ongoing assessment enables nurse to determine specific components of skill that the patient or family easily complete.
- Oxygen concentrators require electricity to work. Continuous oxygen therapy must not be interrupted.
- Hypoxia occurs at home despite use of oxygen therapy. Worsening of a patient's physical condition or another underlying condition such as a change in respiratory status can cause hypoxia.
- Ensure readily available assistance for patients with home oxygen systems.
- Many municipalities require that patients with home oxygen equipment notify emergency medical services (EMS) before bringing the equipment home. When there is a power outage, EMS calls the home, and in some cases the home is on a priority list for having power restored.
- Reduces transmission of infection.
- Prevents injury from improper placement of oxygen equipment.
- Demonstration is reliable technique for teaching psychomotor skill (Falvo, 2004) and encourages patient to ask questions.
- Teaches psychomotor skills and enables a patient to ask questions.
- Turns on oxygen. Keep wrench available.
- Verifies adequate oxygen supply for patient use.
- Provides power source.
- Starts concentrator motor.
- Alarm turns off when desired pressure inside concentrator is reached.
- Verifies adequate oxygen supply.
- Ambulatory tanks of liquid oxygen must be filled when empty.

Critical Decision Point: Fill ambulatory tanks only when they are empty. Liquid oxygen is stored at or below -297°F inside the reservoir, and the temperature inside the ambulatory tank is warmer. If cold oxygen from the reservoir mixes with warmer oxygen left in the ambulatory tank, the ambulatory tank may malfunction.

(3) Refilling oxygen tank:

- (a) Wipe both filling connectors with a clean, dry, lint-free cloth.
 - (b) Turn off flow selector of ambulatory unit.
 - (c) Attach ambulatory unit to stationary reservoir by inserting adapter from ambulatory tank into adapter of stationary reservoir.
- Removes dust and moisture from system.
 - Secures connections.

► SKILL 38-5 Using Home Oxygen Equipment—cont'd

- (d) Open fill valve on ambulatory tank, and apply firm pressure to top of stationary reservoir (see Step 8C(3)(d) illustration). Stay with unit while it is filling. You will hear a loud hissing noise. The tank fills in about two minutes.

Step 8C(3)(d) Fill valve on ambulatory tank is open while applying firm pressure to top of ambulatory unit.

- (e) Disengage ambulatory unit from stationary reservoir when hissing noise changes and vapour cloud begins to form from stationary unit.
- (f) Wipe both filling connectors with a clean, dry, lint-free cloth.

- Prevents leaking of oxygen during filling process. If oxygen leaks during filling process, the connection between ambulatory tank and reservoir will ice up and stick together.

- Overfilling causes the ambulatory unit to malfunction from high pressure in the tank.
- Ice sometimes forms during filling. Wiping removes moisture from oxygen system.

Critical Decision Point: If ambulatory unit does not separate easily, valves from the reservoir and ambulatory unit may be frozen together. Wait until the valves warm to disengage (about 5–10 minutes). Do not touch any frosted areas because contact with skin may cause skin damage from frostbite.

9. Connect oxygen delivery device to oxygen system.
 10. Adjust to prescribed flow rate (L/min).
 11. Place oxygen delivery device on patient. Ensure patient has two sets of oxygen delivery devices and tubing.
 12. Perform hand hygiene.
 13. Instruct patient and family not to change oxygen flow rate.
 14. Guide the patient and family as they perform each step. Provide written material for reinforcement and review.
 15. Instruct the patient or family to notify physician if signs or symptoms of hypoxia or respiratory tract infection occur.
 16. Discuss emergency plan for power loss, natural disaster, and acute respiratory distress. Have patient or family call 911 and notify physician and home care agency.
 17. Instruct patient in safe home oxygen practices including placing "No Smoking/Oxygen in Use" signs at each entrance to the home, not allowing smoking in the home, keeping oxygen tanks away from open flames, and storing tanks upright.
 18. Monitor rate of oxygen delivery.
- Connects oxygen source to delivery system.
 - Ensures appropriate oxygen prescription.
 - Delivers oxygen to patient. Extra devices used when equipment is cleaned or in case of malfunction.
 - Reduces transmission of microorganisms.
 - Provides prescribed amount of oxygen. Exceeding prescribed oxygen may be harmful (e.g., COPD).
 - Allows nurse to correct errors in technique and discuss their implications.
 - Respiratory tract infections increase oxygen demand and may affect oxygen transfer from lungs to blood. They may cause severe exacerbation of patient's pulmonary disease.
 - Ensures appropriate response and can prevent worsening of patient's condition.
 - Ensures safe use of oxygen in the home and prevents injury to patient and family.
 - Determines if patient is regulating oxygen at prescribed rate.

Continued

► SKILL 38-5 Using Home Oxygen Equipment—cont'd

Unexpected Outcomes

Patient reports no oxygen flow

Unable to fill portable liquid oxygen from main source

Related Interventions

- Check tank pressure gauge. If level of oxygen is low, refill tank if portable, or provide alternative source of oxygen, such as concentrator or H cylinder.
- Notify home oxygen supplier of need for refill.
- Reassure patient and family.
- Check to see that portable tank is connected correctly.
- Determine if valve is frozen.
- Contact home oxygen supplier for service visit.
- Provide alternative oxygen source if necessary.

Recording and Reporting

- Record the patient's and family's ability to safely use the home oxygen equipment. Report the type of home oxygen equipment to be used, the patient's and family's understanding of how to use the equipment, knowledge of safety guidelines and unexpected outcomes, and ability to demonstrate proper use of the oxygen delivery device.

Emphasis is placed on ensuring that high-quality CPR is performed (Field et al., 2010, p. S643). Adequate chest compressions require that compressions be provided at the appropriate rate and depth, allowing for complete chest recoil after each compression, minimizing interruptions in compressions, and avoiding excessive ventilation (AHA, 2010; Field et al., 2010, p. S640). The newest development in the 2010 *American Heart Association Guidelines for CPR and Emergency Cardiovascular Care* is a change in the basic life support (BLS) sequence of steps from "A-B-C" (Airway, Breathing, Chest compressions) to "C-A-B" (Chest compressions, Airway, Breathing) for adults and pediatric patients (children and infants, excluding newborns) (AHA, 2010; Field et al., 2010, p. S642).

Restorative and Continuing Care

Restorative and continuing care may emphasize cardiopulmonary reconditioning as a structured rehabilitation program. **Cardiopulmonary rehabilitation** is actively helping the patient to achieve and maintain an optimal level of health through controlled physical exercise, nutrition counselling, relaxation and stress management techniques, prescribed medications and oxygen, and compliance. As physical reconditioning occurs, the patient's complaints of dyspnea, chest pain, fatigue, and activity intolerance should decrease. The patient's anxiety, depression, or somatic concerns also often decrease. The patient and the rehabilitation team define the goals of rehabilitation.

Hydration. Maintenance of adequate systemic hydration keeps mucociliary clearance normal. In patients with adequate hydration, pulmonary secretions are thin, white, watery, and easily removable with minimal coughing. Excessive coughing to clear thick, tenacious secretions is fatiguing and energy depleting. The best way to maintain thin secretions is to provide a fluid intake of 1500 to 2000 mL/day unless contraindicated by cardiac status. The colour, consistency, and ease of secretion expectoration can determine the adequacy of hydration.

Coughing Techniques. Coughing is effective for maintaining a patent airway. Coughing enables the patient to remove secretions from both the upper and lower airways. The normal series of events in the cough mechanism are deep inhalation, closure of the glottis, active contraction of the expiratory muscles, and glottis opening. Deep inhalation increases

the lung volume and airway diameter, allowing the air to pass through partially obstructing mucous plugs or other foreign matter. Contraction of the expiratory muscles against the closed glottis causes a high intrathoracic pressure to develop. When the glottis opens, a large flow of air is expelled at a high speed, providing momentum for mucus to move to the upper airways, where it can be expectorated or swallowed.

The effectiveness of coughing is evaluated by sputum expectoration, the patient's report of swallowed sputum, or clearing of adventitious sounds by auscultation. Patients with chronic pulmonary diseases, upper respiratory tract infections, and lower respiratory tract infections should be encouraged to deep-breathe and cough at least every two hours while awake. Patients with a large amount of sputum should be encouraged to cough every hour while awake and every two to three hours while asleep until the acute phase of mucus production has ended. Coughing techniques include deep breathing and coughing for the postoperative patient, cascade, huff, and quad coughing.

With the *cascade cough*, the patient takes a slow, deep breath and holds it for two seconds while contracting expiratory muscles. Then the patient opens the mouth and performs a series of coughs throughout exhalation, thereby coughing at progressively lowered lung volumes. This technique promotes airway clearance and a patent airway in patients with large volumes of sputum.

The *huff cough* stimulates a natural cough reflex and is generally effective only for clearing central airways. While exhaling, the patient opens the glottis by saying the word "huff." With practice, the patient inhales more air and may be able to progress to the cascade cough.

The *quad cough* technique is used for patients without abdominal muscle control, such as those with spinal cord injuries. While the patient breathes out with a maximal expiratory effort, the patient or nurse pushes inward and upward on the abdominal muscles toward the diaphragm, causing the cough.

Respiratory Muscle Training. Respiratory muscle training improves muscle strength and endurance, resulting in improved activity tolerance. Respiratory muscle training may prevent respiratory failure in patients with COPD.

One method for respiratory muscle training is the incentive spirometer resistive breathing device (ISRBD). Resistive breathing is achieved by placing a resistive breathing device

into a volume-dependent incentive spirometer. Muscle training is achieved when the patient uses the ISRD on a scheduled routine (e.g., twice a day for 15 minutes or four times a day for 15 minutes).

Breathing Exercises. Breathing exercises include techniques to improve ventilation and oxygenation. The three basic techniques are deep breathing and coughing exercises, pursed-lip breathing, and diaphragmatic breathing. Deep breathing and coughing exercises are routine interventions for postoperative patients (see Chapter 48).

Pursed-Lip Breathing. Pursed-lip breathing involves deep inspiration and prolonged expiration through pursed lips to prevent alveolar collapse. While the patient is sitting up, instruct the patient to take a deep breath and to exhale slowly through pursed lips, as if blowing through a straw. Have the patient blow through a straw into a glass of water to learn the technique. Patients need to gain control of the exhalation phase so that it is longer than inhalation. The patient is usually able to perfect this technique by counting the inhalation time and gradually increasing the count during exhalation. In studies using pulse oximetry as a feedback tool, patients have been able to demonstrate an increase in their arterial oxygen saturation during pursed-lip breathing.

Diaphragmatic Breathing. Diaphragmatic breathing is more difficult and requires the patient to relax intercostal and accessory respiratory muscles while taking deep inspirations. The patient concentrates on expanding the diaphragm during controlled inspiration and is taught to place one hand flat below the breastbone and above the waist, and the other hand 2 to 3 cm below the first hand. The patient is asked to inhale while the lower hand moves outward during inspiration. The patient observes for inward movement as the diaphragm ascends. These exercises are initially taught with the patient in the supine position and then practised while the patient sits and stands. The exercise is often used with the pursed-lip breathing technique.

Diaphragmatic breathing is also useful for patients with pulmonary disease, for postoperative patients, and for women in labour to promote relaxation and provide pain control. The exercise improves efficiency of breathing by decreasing air trapping and reducing the work of breathing.

❖ Evaluation

Nursing interventions and therapies are evaluated by comparing the patient's progress with the goals and expected outcomes of the nursing care plan. Evaluate the actual care given to the patient by the health care team on the basis of the expected outcomes (Figure 38-20).

Patient Care

The patient is the only one who can evaluate his or her degree of breathlessness. The patient should be asked to rate breathlessness on a scale of 1 to 10, with 1 being no shortness of breath and 10 being severe shortness of breath. Arterial blood gas levels, pulmonary function tests, vital signs, ECG tracings, and physical assessment data provide objective measurement of the success of therapies and treatments. Outcomes are compared with expected outcomes to determine the patient's health status. Continuous evaluation helps to determine whether new or revised therapies are required and if new nursing diagnoses have developed and require a new plan of care.

Figure 38-20 Critical thinking model for oxygenation evaluation.

When nursing measures directed to improve oxygenation are unsuccessful, immediately modify the nursing care plan. Do not hesitate to notify the physician about a patient's deteriorating oxygenation status. Prompt notification can avoid an emergency situation or even the need for CPR.

Patient Expectations

It is important to ask patients if their expectations of care have been met. For example, you can ask the patient, "Do you feel like you will be able to use the breathing techniques we have practised at home?" If the patient does not think this will work at home, then the patient's expectations for care management have not been met.

You should ask the patient whether all questions and needs have been met. If not, spend more time understanding what the patient wants and needs to meet his or her expectations. Working closely with the patient will enable you to redefine those patient expectations that can be realistically met within the limitations of the patient's condition and treatment.

❖ KEY CONCEPTS

- The primary function of the heart is to deliver deoxygenated blood to the lungs for oxygenation and to deliver oxygen and nutrients to the tissues.
- Preload, afterload, contractility, and heart rate alter cardiac output.

- Cardiac dysrhythmias are classified by cardiac activity and site of impulse origin.
- The primary function of the lungs is to transfer oxygen from the atmosphere into the alveoli and to transfer carbon dioxide out of the body as a waste product.
- Ventilation is the process of providing adequate oxygenation from the alveoli to the blood.
- Compliance, or the ability of the lungs to expand and contract, depends on the function of musculoskeletal and neurological systems and on other physiological factors.
- The process of inspiration (active process) and expiration (passive process) is caused by changes in intrapleural and intra-alveolar pressures and lung volumes.
- Respiration is controlled by the central nervous system and by chemicals within the blood.
- Decreased hemoglobin levels alter the patient's ability to transport oxygen.
- Impaired chest wall movement reduces the level of tissue oxygenation.
- Hyperventilation is a respiratory rate greater than that required to maintain normal levels of carbon dioxide.
- Hypoventilation causes carbon dioxide retention.
- Hypoxia occurs if the amount of oxygen delivered to tissues is too low.
- The health history and assessment includes information about the patient's cough, dyspnea, fatigue, wheezing, chest pain, environmental exposures, respiratory infection, cardiopulmonary risk factors, and use of medications.
- Diagnostic and laboratory tests may be needed to complete the database for a patient with decreased oxygenation.
- Breathing exercises improve ventilation, oxygenation, and sensations of dyspnea.
- Nebulization delivers small drops of water or particles of medication to the airways.
- Chest physiotherapy includes postural drainage, percussion, and vibration to mobilize pulmonary secretions.
- Coughing and suctioning techniques are used to maintain a patent airway.
- Oxygen therapy is used to improve levels of tissue oxygenation and is delivered by a nasal cannula, various oxygen masks, or the use of an artificial airway.

✦ CRITICAL THINKING EXERCISES

1. Ms. Delgado is a 56-year-old postmenopausal woman with a history of hypertension. She presents to her primary care office with complaints of nausea, indigestion, increased fatigue, and shortness of breath with increased activity for the past 16 hours. What questions would you ask Ms. Delgado in the nursing health history?
2. Mr. Kwan has recently immigrated to Canada. He comes to the clinic because he has been increasingly fatigued, has a persistent cough, has been losing weight, and awakens at night with sweats. What questions would be important to ask when completing the nursing health history?
3. Mrs. Leblanc, age 45 years, has been admitted to the hospital with community-acquired pneumonia. She has a productive cough, fever, chills, crackles and wheezes on auscultation of her chest, and a heart rate of 104 beats per minute. What nursing diagnosis would you consider for this patient? What nursing interventions would be appropriate for her? What health promotion interventions need to be initiated before discharge from the hospital?
4. Mr. Chen Lee, age 72 years, is on a medical unit for a recent diagnosis of COPD. He uses his call bell to indicate that he feels short of breath. His respiratory rate is 32 breaths per minute and oxygen saturation is 86% on room air. What immediate nursing interventions would you initiate?

✦ REVIEW QUESTIONS

1. Patients with anemia may complain of
 1. Fatigue
 2. Increased activity tolerance
 3. Decreased breathlessness
 4. Increased appetite
2. The most common toxic inhalant that decreases the oxygen-carrying capacity of blood is
 1. Carbon dioxide
 2. Carbon monoxide
 3. Nitrogen
 4. Mustard gas
3. Conditions such as shock and severe dehydration resulting from extracellular fluid loss and reduced circulating blood volume cause
 1. Hypovolemia
 2. Hypervolemia
 3. Uncontrolled bleeding
 4. Hypoxia
4. Fever increases the tissues' need for oxygen, and as a result
 1. Carbon dioxide decreases
 2. Cyanosis occurs
 3. Carbon dioxide increases
 4. Muscle mass increases
5. Left-sided heart failure is an abnormal condition characterized by
 1. Impaired functioning of the left ventricle
 2. Impaired functioning of the left atrium
 3. Lowered cardiac pressures
 4. Increased cardiac output
6. Right-sided heart failure results from
 1. Impaired functioning of the right ventricle
 2. Impaired functioning of the right atrium
 3. Severe weight loss
 4. Lowered pulmonary vascular resistance
7. Cyanosis, the blue discoloration of the skin and mucous membranes caused by the presence of desaturated hemoglobin in capillaries, is a(an)
 1. Early sign of hypoxia
 2. Late sign of hypoxia
 3. Reliable measure of oxygenation status
 4. Non-life-threatening event
8. A person who starts smoking in adolescence and continues to smoke into middle age
 1. Has an increased risk for cardiopulmonary disease and lung cancer
 2. Has an increased risk for obesity and diabetes
 3. Has an increased risk for stress-related illnesses
 4. Has an increased risk for alcoholism

9. A simple and cost-effective method for reducing the risks of stasis of pulmonary secretions and decreased chest wall expansion is
 1. Oxygen humidification
 2. Chest physiotherapy
 3. Frequent changes of position
 4. Anti-infectives
10. The most effective position for patients with cardiopulmonary diseases is the
 1. Supine position
 2. Prone position
 3. High Fowler's
 4. 45-degree semi-Fowler's
11. A patient has a suspected tension pneumothorax following the insertion of a chest tube. What action is considered a nursing priority?
 1. Assess the chest tube to ensure it is not clamped or occluded.
 2. Cross-clamp the chest tube close to the patient's chest.
 3. Change the dressing using non-occlusive material.
 4. Instruct the patient to deep-breathe and cough.
12. Which of the following statements best describes the correct method for artificial airway suctioning?
 1. Use clean gloves to complete the procedure.
 2. Insert the catheter 1-2 cm during expiration.
 3. Lightly coat 2-3 cm of catheter with water-soluble lubricant.
 4. Apply intermittent suction while withdrawing the catheter.

✦ RECOMMENDED WEB SITES

Canadian Lung Association: <http://www.lung.ca/>

The Canadian Lung Association is the umbrella group for the 10 provincial lung associations. Its goal is to promote research, education, and healthy living in order to combat lung disease.

Health Canada—Cardiovascular Disease Division: <http://www.hc-sc.gc.ca/hc-ps/dc-ma/index-eng.php>

This Web site for Health Canada provides links, information, and resources on the topic of cardiovascular health.

Heart and Stroke Foundation of Canada: <http://www.heartandstroke.ca>

The Heart and Stroke Foundation is a national voluntary, non-profit organization whose mission is to improve the health of Canadians by preventing heart disease and stroke through research, health promotion, and advocacy.

Fluid, Electrolyte, and Acid-Base Balances

Written by Darlaine Jantzen, RN, MA, PhD

Based on the original chapter by Linda Felver, RN, PhD

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Describe the distribution, composition, movement, and regulation of body fluids.
- Describe the regulation and movement of major electrolytes.
- Describe the processes involved in acid-base balance.
- Identify factors that affect normal fluid, electrolyte, and acid-base balances.
- Discuss the clinical assessments for fluid, electrolyte, and acid-base balances.
- Describe laboratory studies associated with fluid, electrolyte, and acid-base balances.
- Identify and discuss nursing interventions for patients with fluid, electrolyte, and acid-base imbalances.
- Discuss the purpose of and procedure for initiating, maintaining, and discontinuing peripheral vascular access devices.
- Discuss the purpose and nursing care related to central vascular access devices, including preventing and recognizing associated complications.
- Calculate the intravenous flow rate.
- Discuss complications associated with intravenous therapy.
- Discuss the purpose of and procedure for initiating a blood transfusion and interventions to manage transfusion reaction.

media resources

Fluid, electrolyte, and acid-base balances within the body are essential for normal body function (Box 39-1). These balances are maintained by ingestion, distribution, and excretion of water and electrolytes and by respiration. Within the body, these balances are maintained by the renal, pulmonary, and buffer systems. Imbalances may be caused by many factors, including altered intake, illness, or excessive losses, such as exercise-induced diaphoresis. These imbalances affect physiological processes at the cellular, tissue, and system levels of the body; therefore, understanding the mechanisms that contribute to fluid, electrolyte, and acid-base balances is essential to nursing practice.

Scientific Knowledge Base

Water is the largest single component of the body. The average adult's weight is 60% fluid; however, this amount varies with age, gender, and weight. A healthy, mobile, well-oriented adult can usually maintain normal fluid, electrolyte, and acid-base balances with renal, hormonal, and neural functions (McCance & Huether, 2010, p. 96).

BOX 39-1 NURSING STORY

Harold's Waterworks

Susanne Walter works on a medical unit in a small city. One evening, Harold Short, aged 75, was admitted to Susanne's unit after his friends found him weak and confused at home after not showing up to his weekly bridge club meeting. Harold had been managing well on his own, still caring for his home and garden with only occasional assistance with heavy jobs from his son. Harold's wife passed away four years previously. Harold was known to his physician but rarely made appointments. Over the fall, Harold's friends had noted that he complained about problems with his "waterworks" but was otherwise well.

On Susanne's initial assessment, she concluded that Harold had been minimizing his fluid intake to avoid having to get up "every 10 minutes" at night. Over the 24 hours before admission, he had not been able to get out of his bedroom because of weakness and "the other people rambling around." Susanne observed that Harold had moments of uncharacteristic confusion during his interview. Susanne assessed Harold's venous filling because she was aware that assessing skin turgor is less reliable in older adults. His blood pressure was low, and his heart rate was elevated. His laboratory tests revealed hypernatremia (sodium 148 mmol/L) with elevated blood urea nitrogen (18.0 mmol/L) and creatinine (130 mmol/L). Susanne palpated a distended bladder, conducted a bladder scan, and determined that Harold had urinary retention, which led him to avoid fluids.

After Harold was catheterized and treated with intravenous and oral fluid, his blood work and mental status returned to normal. Susanne cared for Harold over four shifts and developed a therapeutic nurse-patient relationship. Before Harold's discharge, Susanne educated Harold about the importance of fluid intake for his well-being and to drink more fluids earlier in the day to avoid having to get up as often at night. She also educated Harold's family and friends regarding how to support Harold to increase his fluid intake during the day, in addition to the signs and symptoms of fluid and electrolyte imbalances. Susanne advocated for a urology consultation regarding Harold's urinary retention. Although Harold refused to "carry around a drinking bottle like those young folks," he expressed clear understanding regarding his fluid and electrolyte health.

Distribution of Body Fluids

Body fluids are distributed in two distinct compartments, one containing intracellular fluid and the other containing extracellular fluid. **Intracellular fluid (ICF)** comprises all fluid within body cells, accounting for approximately 66% of total body water and 40% of body weight (McCance & Huether, 2010, p. 97).

Extracellular fluid (ECF), all the fluid outside cells, is divided into three smaller compartments: interstitial fluid, intravascular fluid, and transcellular fluids. **Interstitial fluid**, including lymph, is the fluid between the cells and outside the blood vessels. **Intravascular fluid** is blood plasma. **Transcellular fluid**, separated from other fluid by epithelium, includes cerebrospinal, pleural, peritoneal, and synovial fluids and the fluids in the gastrointestinal tract (McCance & Huether, 2010, p. 97).

Composition of Body Fluids

Electrolytes are important **solutes** in all body fluids. An electrolyte, when dissolved in an aqueous solution, separates into **ions** and is able to carry an electrical current (Martini & Nath, 2009). Positively charged electrolytes are **cations** (e.g., sodium $[Na^+]$, potassium $[K^+]$, calcium $[Ca^{2+}]$). Negatively charged electrolytes are **anions** (e.g., chloride $[Cl^-]$, bicarbonate $[HCO_3^-]$, sulphate $[SO_4^{2-}]$). Electrolytes are vital to many body functions.

The body carefully regulates electrolyte concentration (Table 39-1). The value millimoles per litre (mmol/L) represents the amount of the specific electrolyte (solute) dissolved in a litre of fluid (**solution**). The solution in which a solute is dissolved is called a **solvent**. Electrolyte concentration within fluid compartments is influenced by electrical charge. During normal physiological processes, ions are exchanged for other ions with the same electrical charge.

Electrolytes are ingested, often in the form of bulk and trace minerals or salts, and then utilized for basic physiological processes, stored for future use, or excreted. These electrolytes are important for maintaining osmotic concentrations in body fluids. They are also necessary for enzyme reactions, nerve impulses, muscle contraction, and metabolism. In addition, some minerals contribute to the regulation of hormone production and strengthening of skeletal structures.

► TABLE 39-1

Electrolyte Concentration in Extracellular Fluid (Serum Levels)

Electrolyte	Extracellular Fluid Concentration (mmol/L)
Sodium (Na^+)	136–145
Potassium (K^+)	3.5–5.0
Calcium (Ca^{2+})	2.25–2.75
Bicarbonate (HCO_3^-)	22–26 (arterial), 24–30 (venous)
CO_2	23–30 (venous)
Chloride (Cl^-)	98–106
Magnesium (Mg^{2+})	0.65–1.05
Phosphate (PO_4^{3-})	0.97–1.45

Figure 39-1 Osmosis: Water moving across a semipermeable membrane.

Movement of Body Fluids

Fluids and electrolytes constantly shift between compartments to facilitate body processes such as tissue oxygenation, acid–base balance, and urine formation. Because cell membranes separating the body fluid compartments are selectively permeable, water can pass through them easily. However, most ions and molecules pass through them more slowly. Fluids and solutes move across these membranes by four processes: osmosis, diffusion, filtration, and carrier-mediated transport.

Osmosis. Osmosis is the movement of water through a semipermeable membrane from an area of lesser solute concentration to an area of greater solute concentration in an attempt to equalize concentrations on both sides of the membrane (Figure 39-1). A semipermeable membrane allows water to pass through while remaining impermeable to most solutes. The rate of osmosis depends on the concentration of the solutes in the solution, temperature of the solution, electrical charges of the solutes, and differences between the osmotic pressures exerted by the solutions. The concentration of a solution is measured in osmols, which reflect the amount of a substance in solution in the form of molecules, ions, or both. One example of osmosis is the action of osmotic laxatives. These laxative salts are poorly absorbed through the intestinal lining and therefore draw water into the intestinal lumen, causing an accumulation of water and therefore softened stool. The swelling also stretches the intestine, stimulating peristalsis (Lehne, 2010).

Osmotic pressure is the pressure needed to counter the movement of water (solvent) across a semipermeable membrane from a low concentration to high concentration of solutes. A solution with a high solute concentration has a high osmotic pressure and draws water into itself. If the concentration of the solute is greater on one side of the semipermeable membrane, the rate of osmosis is faster, and solvent rapidly transfers across the membrane. This continues until equilibrium is reached.

Plasma proteins affect the blood's osmotic pressure. The three main classes of plasma proteins are albumins, globulins, and fibrinogen (Martini & Nath, 2009). Because albumin, produced in the liver, makes up the greatest proportion of plasma proteins, it exerts **colloid osmotic pressure** or oncotic pressure. This oncotic pressure tends to keep fluid in the intravascular compartment by pulling water from the interstitial space back into the capillaries.

Diffusion. Diffusion is the movement of ions and molecules in a solution across a semipermeable membrane from an

Figure 39-2 Diffusion: Particles moving across a semipermeable membrane from high concentration to lower concentration.

area of higher concentration to an area of lower concentration (Figure 39-2). The result is an even distribution of the solute in a solution. The rate of diffusion is affected by the molecule size, concentration, and temperature of a solution. The larger the molecule is and the cooler the solution is, the slower the rate of diffusion is. The difference between the two concentrations is known as a **concentration gradient**. Perfume permeating a room and a drop of food colouring moving through a glass of water are common examples of diffusion. A physiological example is the movement of oxygen (O_2) and carbon dioxide (CO_2) between the alveoli and blood vessels in the lungs.

Filtration. Filtration is the process by which water and diffusible substances move together in response to fluid pressure, moving from an area of higher pressure to one of lower pressure. This process is active in capillary beds, where **hydrostatic pressure** differences determine the movement of water (Figure 39-3). Problems occur when hydrostatic pressure is increased on the venous side of the capillary bed, as occurs in heart failure. The normal movement of water from the interstitial space into the intravascular space by filtration is then reversed. This results in an accumulation of excess fluid in the interstitial space, known as **edema**. Filtration is also very important for urine formation as water and solutes are carried across the wall of the glomerular capillaries by hydrostatic or blood pressure. Falling blood pressure affects this process.

Carrier-Mediated Transport. Carrier-mediated transport moves molecules across the plasma membrane. This process may be active or passive. **Facilitated diffusion** and **active transport** are two examples of carrier mediate transport. When insulin, a carrier protein, binds to glucose, it is able to carry it across the cell membrane. This is an example of facilitated diffusion. Active transport requires energy to move materials across cell membranes against a concentration gradient. The sodium-potassium pump is an example of active transport (Figure 39-4).

Regulation of Body Fluids

Body fluids are regulated by fluid intake, hormonal controls, and fluid output, in order to maintain **homeostasis**. Homeostasis, is essential for survival (Clancy & McVicar, 2007b). In health, the body is able to respond to changes in the ECF. The primary hormones that regulate fluid are antidiuretic hormone, aldosterone, and natriuretic peptides (Martini & Nath, 2010, p. 871).

Figure 39-3 An example of filtration and hydrostatic pressure.

Figure 39-4 The sodium–potassium pump. As sodium diffuses into the cell and potassium is pumped out of the cell, active transport delivers sodium back to the extracellular compartment and potassium back to the intracellular compartment. *ATP*, adenosine triphosphate.

Fluid Output Regulation. Fluid output occurs through four organs of water loss: the kidneys, the skin, the lungs, and the gastrointestinal tract. The kidneys are the major regulatory organs of fluid balance. They receive approximately 180 L of plasma to filter each day and produce 1200 to 1500 mL of urine (Table 39-2).

Insensible water loss is continuous, gradual movement of water from the respiratory and skin epitheliums, amounting to about 20 to 25 mL/hour (Martini & Nath, 2009). The lungs expire about 400 mL of water daily, whereas insensible skin perspiration losses are approximately 600 mL/day. This insensible water loss may increase in response to changes in respiratory rate and depth. In addition, devices for giving oxygen can increase insensible water loss from the lungs.

Fever may increase insensible water loss. Visible or **sensible water loss** from the skin varies greatly depending on the sweat glands. Water loss from the skin is regulated by the sympathetic nervous system, which activates sweat glands.

The gastrointestinal tract plays a vital role in fluid regulation. Every day, approximately 8 L of fluid is moved into the gastrointestinal tract and then returns to the ECF (Day et al., 2010). Of the 3 to 6 L that the average adult loses each day, only

TABLE 39-2

Adult Average Daily Fluid Gains and Losses

Type of Fluid	Change (mL)
Fluid Gains	
Oral fluids	1100–1400
Solid foods	800–1000
Metabolism	300
Total gains	2200–2700
Fluid Losses	
Kidneys	1200–1500
Skin	500–600
Lungs	400
Gastrointestinal tract	100–200
Total losses	2200–2700

100 to 200 mL is lost through the feces, under normal conditions, because most of the fluid is reabsorbed in the small intestine. However, in the presence of a disease process, diarrhea for example, the gastrointestinal tract may become the site of a large amount of fluid loss. This loss may have a significant impact on maintaining normal fluid regulation.

Fluid Intake Regulation. Fluid intake is regulated primarily through the thirst mechanism. The thirst control centre is located within the brain's hypothalamus. Thirst is one of the major factors that determines fluid intake. **Osmoreceptors** continually monitor the serum osmotic pressure, and when **osmolality** increases, nerves cells in the subfornical organ (SFO) and hypothalamus are stimulated (Patton & Thibodeau, 2010). An increase in plasma sodium increases the osmotic pressure and stimulates the thirst mechanism. Increased plasma osmolality can occur with any condition that interferes with the oral ingestion of fluids or with the intake of hypertonic fluids. The thirst centre will also be stimulated when excess fluid is lost and **hypovolemia** occurs, as in excessive vomiting and hemorrhage. In addition, stimulation of the renin–angiotensin–aldosterone mechanism, potassium depletion, psychological factors, and oropharyngeal dryness initiate the sensation of thirst (Figure 39-5).

The average adult's fluid intake is about 2200 to 2700 mL per day; oral intake accounts for 1100 to 1400 mL, solid foods for about 800 to 1000 mL, and oxidative metabolism for 300 mL daily. Patients must be in an alert state to maintain their fluid intake independently. Infants, patients with neurological or psychological problems, and some older adults who are unable

Figure 39-5 Stimuli affecting the thirst mechanism.

to perceive or respond to the thirst mechanism are at risk for dehydration.

Hormonal Regulation. Antidiuretic hormone (ADH) is stored in the posterior pituitary gland and is released in response to changes in blood osmolality. The osmoreceptors in the hypothalamus are stimulated to release ADH when the osmolality increases. ADH promotes water conservation by acting directly on the renal tubules and collecting ducts to make them more permeable to water. This, in turn, causes water to return to the systemic circulation, which dilutes the blood and decreases its osmolality. As the body attempts to compensate, the patient will experience a temporary decrease in urinary output. When the blood has been sufficiently diluted, the osmoreceptors stop the release of ADH and urinary output is restored. ADH also stimulates the thirst centre to promote fluid intake.

Aldosterone is released by the adrenal cortex in response to increased plasma potassium or falling sodium levels or as part of the renin–angiotensin–aldosterone system to counteract hypovolemia. To resolve hypovolemia, renin is released from the kidney in response to sympathetic nervous system stimulation and decreased renal blood flow, initiating a cascade of physiological and endocrine processes, one of which is the release of aldosterone. Aldosterone acts on the distal portion of the renal tubule to increase the reabsorption (saving) of sodium and the secretion and excretion of potassium and hydrogen.

Natriuretic peptides respond to increases in circulating blood volume. They are released from cardiac muscle cells and act on the peripheral vasculature, other hormones, and the kidney to facilitate diuresis. Natriuretic peptides increase sodium excretion and fluid loss while reducing thirst and blocking the release of ADH and aldosterone.

Regulation of Electrolytes

For normal cell function and human well-being, the body maintains a normal balance of electrolytes in the ECF and ICF in spite of changes in intake and loss. This is accomplished primarily through regulation of absorption in the gastrointestinal tract and of excretion through the kidneys. Although fluid and electrolyte balances are inextricably linked, it is important to explore electrolyte balance separately.

Cations. Major cations within the body fluids are sodium, potassium, calcium, and magnesium (Mg^{2+}). Cations

interchange when one cation leaves the cell and is replaced by another. This occurs because cells tend to maintain electrical neutrality.

Sodium Regulation. Sodium is the most abundant cation (90%) in ECF and therefore exerts the greatest influence on the ECF osmotic concentration and water balance. Normally, the intake and output of sodium is between 1.2 g and 3.3 g daily. With an increase in sodium intake, and therefore an increase in ECF sodium content, water enters the ECF by osmosis. Therefore, increased sodium intake results in increased blood volume rather than significant changes in ECF sodium concentration.

The body continually responds to small changes in sodium content. Excessive perspiration and oral intake of water, for example, result in high sodium loss. When this occurs, ADH is reduced in order to maintain homeostasis, and water excretion increases in order to maintain osmotic concentration. However, if the regulation of sodium concentration requires a large change in ECF volume, baroreceptors are stimulated to regulate fluid volumes and blood pressure (Martini & Nath, 2009). Sodium ions are also major contributors to nerve impulse transmission, regulation of acid–base balance, and cellular chemical reactions. The normal extracellular sodium concentration is 136 to 145 mmol/L (Pagana & Pagana, 2010). Sustained or severe problems with sodium concentration result in high sodium, above 145 mmol/L (hypernatremia), or low sodium, below 135 mmol/L (hyponatremia).

Potassium Regulation. Potassium is the major electrolyte and principal cation in the intracellular compartment (Martini & Nath, 2009). The majority (98%) of potassium content is in the ICF. Because the potassium concentration of ECF is relatively low, the cells expend energy to maintain the potassium content of ICF. Potassium is regulated by dietary intake and strongly affected by aldosterone. Extracellular potassium concentration is affected by many complex mechanisms, including those of dietary intake and renal excretion. Renal excretion is regulated by changes in potassium concentration, changes in the acidity or alkalinity of a fluid (pH measurements), sodium reabsorption, and aldosterone levels (Martini & Nath, 2009). The body conserves potassium poorly, so any condition that increases urine output decreases the serum potassium concentration.

Potassium regulates many metabolic activities and is necessary for glycogen deposits in the liver and skeletal muscle, transmission and conduction of nerve impulses, normal cardiac conduction, and skeletal and smooth muscle contraction. The normal range for serum potassium concentrations is 3.5 to 5 mmol/L.

Calcium Regulation. Calcium is stored in bone, plasma, and body cells. Ninety-nine percent of calcium is located in bone, and only 1% is located in ECF. Approximately 50% of calcium in the plasma is bound to protein, primarily albumin, and 40% is free ionized calcium. The remaining small percentage is combined with nonprotein anions such as phosphate (PO_4^{3-}), citrate, and carbonate (Martini & Nath, 2010). Normal serum ionized calcium is 1.0 to 1.2 mmol/L. Normal total calcium is 2.25 to 2.75 mmol/L. Calcium is necessary for bone and teeth formation, blood clotting, hormone secretion, cell membrane integrity, cardiac conduction, transmission of nerve impulses, and muscle contraction.

Magnesium Regulation. Magnesium, the second most abundant intracellular cation, is essential for many intracellular activities, such as enzyme reactions. Magnesium, with a

plasma concentration of 0.65 to 1.05 mmol/L, is important for bone structure and neuromuscular function, including skeletal and cardiac muscle excitability. Serum magnesium is regulated by dietary intake, renal mechanisms, and actions of the parathyroid hormone.

Anions. The three major anions of body fluids are chloride, bicarbonate, and phosphate ions.

Chloride Regulation. Chloride is the major anion in ECF. The transport of chloride follows sodium. Normal concentrations of chloride range from 97 to 107 mmol/L. Serum chloride is regulated by dietary intake and the kidneys. A person with normal renal function who has a high chloride intake will excrete a higher amount of urine chloride.

Bicarbonate Regulation. Bicarbonate is the major chemical base buffer within the body. The bicarbonate ion is found in ECF and ICF. The bicarbonate ion is an essential component of the carbonic acid–bicarbonate buffering system, which is essential to acid–base balance. The kidneys regulate bicarbonate. Normal arterial bicarbonate levels range between 22 and 26 mmol/L; venous bicarbonate is measured as carbon dioxide content, and the normal value is 24 to 30 mmol/L.

Phosphate Regulation. Phosphorus is the major anion in the ICF; however, nearly all the phosphorus in the body exists in the form of phosphate. Phosphate's most important role is within the ICF, where it assists in the formation of high-energy compounds, such as adenosine triphosphate (ATP) and nucleic acids, and in enzyme activity. Similar to magnesium and calcium, phosphate is used and stored in the skeleton. It also functions with calcium to develop and maintain teeth. Calcium and phosphate are inversely proportional; if one rises, the other falls. Phosphate also assists in acid–base regulation, promotes normal neuromuscular action, and participates in carbohydrate metabolism. Phosphate is normally absorbed through the gastrointestinal tract and is regulated by dietary intake, renal and intestinal excretion, and parathyroid hormone. The normal serum phosphorus level is 0.9 to 1.45 mmol/L.

Regulation of Acid-Base Balance

Acid–base balance exists when the rate at which the body produces and gains acids or bases, through cellular metabolism and gastrointestinal absorption, equals the rate at which acids or bases are excreted.

This balance results in a stable concentration of hydrogen ions (H^+) in body fluids that is expressed as the pH value. Hydrogen ions are primarily excreted by the kidneys. A normal hydrogen ion level is necessary to maintain cell membrane integrity and the speed of cellular enzymatic actions.

Arterial blood pH is inversely proportional to the hydrogen ion concentration (i.e., the greater the concentration, the more acidic the solution is and the lower the pH is; the lower the concentration, the more alkaline the solution is and the higher the pH is). The pH is also a reflection of the balance between carbon dioxide, which is regulated by the lungs, and bicarbonate, a base regulated by the kidneys. Normal pH is maintained by chemical buffers, and buffer systems and regulatory mechanisms in the kidneys and lungs. A **buffer** is a substance or group of substances that can absorb or release hydrogen ions to stabilize pH, such as bicarbonate, phosphate, and proteins. Whereas the chemical buffers act immediately, the response by the kidneys may take minutes, and the response in the lung much longer.

Buffers. Buffer systems are combinations of a weak acid and a weak base and are the short-term regulators of acid–base

Figure 39-6 Carbonic acid-to-bicarbonate ratio and pH.

balance. The four main types of buffer systems are protein (amino acids, plasma proteins), hemoglobin (also a protein but unique in its buffering role), carbonic acid (H_2CO_3) and bicarbonate, and phosphate. Other types are the ammonia buffer system, a complex system that occurs in ICF, and the tubular system in the kidneys. All these buffers bind hydrogen ions until they can be permanently removed through the regulatory mechanisms in the lungs and the kidneys.

The carbonic acid–bicarbonate buffer system (Figure 39-6) is used to evaluate acid–base balance, using the arterial blood gas (ABG) test. This system can be expressed as the following:

The carbonic acid–bicarbonate buffer system is the principal buffering system to react to change in the pH of ECF, and it reacts within seconds. Whenever carbon dioxide increases, an increase in hydrogen ions results, and whenever hydrogen ions are produced, more carbon dioxide results (Clancy & McVicar, 2007a). The lungs control the excretion of carbon dioxide, and the kidneys control the excretion of hydrogen and bicarbonate ions.

Another buffer system is the hemoglobin–oxyhemoglobin system within red blood cells (RBCs). This buffer system can have an immediate effect on pH because carbon dioxide diffuses readily into the RBC and forms carbonic acid. The carbonic acid dissociates into hydrogen and bicarbonate ions, the latter of which diffuse into the plasma in exchange for chloride. The hydrogen ions attach to hemoglobin, whereas the carbon dioxide is carried to the lungs, where the reaction is reversed.

Regulatory Mechanisms. When the ability of buffer systems is exceeded, acid–base homeostasis is regulated by the lungs and the kidneys. The lungs adapt rapidly to an acid–base imbalance. Ordinarily, increased levels of hydrogen ions and carbon dioxide provide the stimulus for respiration. When the concentration of hydrogen ions is altered, the lungs react to correct the imbalance by altering the rate and depth of respiration. For example, when metabolic acidosis is present, respirations are increased, resulting in a greater amount of carbon dioxide being exhaled, which results in a decrease in the acidic level; when metabolic alkalosis is present, the lungs retain

carbon dioxide by decreasing the respirations, thereby increasing the acidic level (Martini & Nath, 2009).

The kidneys take from a few hours to several days to regulate acid–base imbalance. They regenerate or reabsorb bicarbonate in cases of acid excess and excrete it in cases of acid deficit. In addition, the kidneys use a phosphate ion to excrete hydrogen ions by forming phosphoric acid (H_3PO_4). Finally, the kidneys use the ammonia mechanism to regulate acid–base balance. In this mechanism, certain amino acids are chemically changed within the renal tubules into ammonia, which, in the presence of hydrogen ions, forms ammonium, which is excreted in the urine, thereby releasing hydrogen ions from the body (McCance & Huether, 2010).

Disturbances in Electrolyte, Fluid, and Acid-Base Balances

Disturbances in electrolyte, fluid, or acid–base balance seldom occur alone and can disrupt normal body processes. For example, when body fluids are lost because of burns, illness, or trauma, the patient is also at risk for electrolyte imbalances. In addition, some untreated electrolyte imbalances (e.g., potassium loss) contribute to acid–base disturbances.

Electrolyte Imbalances. Table 39-3 provides a list of the causes, signs, and symptoms of electrolyte imbalances.

Sodium Imbalances. **Hyponatremia** is a lower-than-normal concentration of sodium in the blood (serum), which can occur with a net sodium loss or net water excess (see Table 39-3). It occurs frequently in seriously ill patients and is the most common electrolyte disturbance among older adults (Soiza et al., 2008). Clinical indicators and treatment depend on the cause of hyponatremia and whether it is associated with a normal, decreased, or increased ECF volume. The usual situation is a loss of sodium without a loss of fluid, which results in a decrease in the osmolality of ECF. Sodium and chloride are not stored in the body; therefore, they must be consumed daily or provided through IV solutions in the ill.

Hypernatremia is a greater-than-normal concentration of sodium in ECF that can be caused by excess water loss or overall sodium excess (see Table 39-3). When hypernatremia occurs, the body attempts to conserve as much water as possible through renal reabsorption.

Potassium Imbalances. **Hypokalemia** is one of the most common electrolyte imbalances (see Table 39-3). Hypokalemia, with potassium levels less than 3.5 mmol/L, results in cardiac arrhythmias, fatigue, and altered muscle activity throughout the body (Day et al., 2010). Because the normal amount of serum potassium is so small, little tolerance for fluctuations exists. The most common cause of hypokalemia is the use of potassium-wasting diuretics such as thiazide and loop diuretics.

Hyperkalemia is a greater-than-normal amount of potassium in the blood. Lethal cardiac arrhythmias result from potassium levels over 5.0 mmol/L, as well as skeletal muscle weakness and paralysis (see Table 39-3). The primary cause of hyperkalemia is renal failure because any decrease in renal function diminishes the amount of potassium the kidney can excrete.

Calcium Imbalances. **Hypocalcemia** represents a drop in serum or ionized calcium. It can result from several illnesses, some of which directly affect the thyroid and parathyroid glands (see Table 39-3). Other causes include prolonged bed rest and renal insufficiency (in which the kidneys' inability to excrete phosphorus causes the phosphorus level to rise and the

calcium level to decline). Signs and symptoms can be related to diminished functioning of the neuromuscular, cardiac, and renal systems.

Hypercalcemia is an increase in the total serum concentration of calcium or ionized calcium. Hypercalcemia is frequently a symptom of an underlying disease, such as malignancy or hyperparathyroidism, resulting in excess bone reabsorption with release of calcium (McCance & Huether, 2010).

Magnesium Imbalances. Disturbances in magnesium levels are summarized in Table 39-3. Symptoms are the result of changes in neuromuscular excitability. **Hypomagnesemia**, a drop in serum magnesium below 0.65 mmol/L, occurs with malnutrition, malabsorption disorders, diarrhea, and alcohol withdrawal. This may cause neuromuscular symptoms, seizures, or cardiac arrhythmias. **Hypermagnesemia**, an increase in serum magnesium levels more than 1.05 mmol/L, depresses skeletal muscles and nerve function. Magnesium may inhibit acetylcholine, thereby causing a sedative effect.

Chloride Imbalances. **Hypochloremia** occurs when the serum chloride level falls below normal. Vomiting or prolonged and excessive nasogastric or fistula drainage can result in hypochloremia because of the loss of hydrochloric acid. The use of loop and thiazide diuretics also results in increased chloride loss as sodium is excreted. When serum chloride levels fall, metabolic alkalosis results as the body adapts by increasing reabsorption of the bicarbonate ion to maintain electrical neutrality.

Hyperchloremia occurs when the serum chloride level rises above normal, which usually occurs when the serum bicarbonate value falls or the sodium level rises. Hypochloremia and hyperchloremia rarely occur as single disease processes but are commonly associated with acid–base imbalance. No single set of symptoms is associated with these two alterations.

Fluid Disturbances. The basic types of fluid imbalances are isotonic and osmolar. Isotonic deficit and excess exist when water and electrolytes are gained or lost in equal proportion. In contrast, osmolar imbalances are losses or excesses of only water, so the concentration (osmolality) of the serum is affected. It is important to recognize that maintaining fluid homeostasis is primarily related to circulatory volume. Hemodynamics respond quickly to changes in the intravascular compartment, followed more slowly by sodium and water balance mechanisms (McCance & Huether, 2010). Table 39-4 lists the causes and signs and symptoms of common fluid disturbances.

Acid-Base Balance. **Arterial blood gas (ABG)** analysis is the best way to evaluate acid–base balance and is based on the carbonic acid–bicarbonate buffer system. Measurement of ABGs involves analysis of six components: pH, PaCO_2 , PaO_2 , oxygen saturation, base excess, and bicarbonate. Deviation from a normal value will indicate that the patient is experiencing an acid–base imbalance.

Measurements of Acidity or Alkalinity of Fluids. The pH reflects hydrogen ion concentration in the body fluids. Even a slight change can be potentially life-threatening. An increase in concentration of hydrogen ion makes a solution more acidic; a decrease makes the solution more alkaline. Normal pH value is 7.35 to 7.45; therefore, a pH value below 7.35 is acidic, and above 7.45 is alkalotic.

PaCO_2 . PaCO_2 is the partial pressure of carbon dioxide in arterial blood and is a reflection of the depth of pulmonary ventilation. The normal range is 35 to 45 mm Hg. A PaCO_2 less than 35 mm Hg is an indication that hyperventilation has occurred. As the rate and depth of respiration increase, more

► TABLE 39-3 Electrolyte Imbalances

Imbalance and Related Causes**Hyponatremia**

GI losses: vomiting, diarrhea, nasogastric suction
 Renal loss: kidney disease resulting in salt wasting; diuretics; adrenal insufficiency
 Skin loss: excessive perspiration; burns
 Psychogenic polydipsia
 Syndrome of inappropriate antidiuretic hormone (SIADH)

Signs and Symptoms

Physical examination: apprehension, personality change, postural hypotension, postural dizziness, abdominal cramping, nausea and vomiting, diarrhea, tachycardia, dry mucous membranes, convulsions, and coma
Laboratory findings: serum sodium level <135 mmol/L, serum osmolality <285 mmol/kg, and urine specific gravity <1.010 (if not caused by SIADH)

Hypernatremia

Excess salt intake: ingestion of large amounts of concentrated salt solutions; iatrogenic administration of hypertonic saline solution parenterally
 Excess aldosterone secretion
 Diabetes insipidus
 Increased sensible and insensible water losses
 Water deprivation

Physical examination: extreme thirst, dry and flushed skin, dry and sticky tongue and mucous membranes, postural hypotension, fever, agitation, convulsions, restlessness, and irritability
Laboratory findings: serum sodium levels >145 mmol/L, serum osmolality >300 mmol/kg, and urine specific gravity >1.030 (if not caused by diabetes insipidus)

Hypokalemia

Use of potassium-wasting diuretics
 Diarrhea, vomiting, or other GI losses
 Alkalosis
 Excess aldosterone secretion
 Polyuria
 Extreme sweating
 Excessive use of potassium-free intravenous solutions
 Treatment of diabetic ketoacidosis with insulin

Physical examination: weakness and fatigue, muscle weakness, nausea and vomiting, intestinal distension, decreased bowel sounds, decreased deep tendon reflexes, ventricular dysrhythmias, paraesthesias, and weak, irregular pulse
Laboratory findings: serum potassium level <3.5 mmol/L; ECG abnormalities (flattened T wave, ST segment depression, U wave); potentiated digoxin effects (e.g., ventricular dysrhythmias)*

Hyperkalemia

Renal failure
 Fluid volume deficit
 Massive cellular damage such as from burns and trauma
 Iatrogenic administration of large amounts of potassium intravenously
 Adrenal insufficiency
 Acidosis, especially diabetic ketoacidosis
 Rapid infusion of stored blood
 Use of potassium-sparing diuretics
 Ingestion of K⁺ salt substitutes

Physical examination: anxiety, dysrhythmias, paraesthesia, weakness, abdominal cramps, and diarrhea
Laboratory findings: serum potassium level >5.0 mmol/L; ECG abnormalities (peaked T wave and widened QRS complex [bradycardia, heart block, dysrhythmias]; eventually, QRS pattern widens and cardiac arrest occurs*)

Hypocalcemia

Rapid administration of blood transfusions containing citrate
 Hypoalbuminemia
 Hypoparathyroidism
 Vitamin D deficiency
 Pancreatitis
 Alkalosis
 Chronic renal failure
 Chronic alcoholism

Physical examination: numbness and tingling of fingers and circumoral (around mouth) region, hyperactive reflexes, positive Trousseau's sign (carpopedal spasm with hypoxia), positive Chvostek's sign (contraction of facial muscles when facial nerve is tapped), tetany, muscle cramps, and pathological fractures (chronic hypocalcemia)
Laboratory findings: serum ionized calcium level <1.05 mmol/L or total serum calcium level <2.25 mmol/L; ECG abnormalities (ventricular tachycardia)

Hypercalcemia

Hyperparathyroidism
 Osteometastasis
 Paget's disease
 Osteoporosis
 Prolonged immobilization
 Acidosis
 Thiazide diuretics

Physical examination: anorexia, nausea and vomiting, weakness, hypoactive reflexes, lethargy, flank pain (from kidney stones), decreased level of consciousness, personality changes, and cardiac arrest
Laboratory findings: serum ionized calcium level >1.30 mmol/L or total serum calcium level >2.75 mmol/L; abnormalities visible on X-ray examination (generalized osteoporosis, widespread bone cavitation, radiopaque urinary stones); elevated blood urea nitrogen level >7.1 mmol/L and elevated creatinine level >106 mmol/L, caused by fluid volume deficit or renal damage caused by urolithiasis; ECG abnormalities (heart block)

Continued

► **TABLE 39-3** Electrolyte Imbalances—cont'd**Imbalance and Related Causes****Hypomagnesemia**

Inadequate intake: malnutrition and alcoholism
 Inadequate absorption or loss: diarrhea, vomiting, nasogastric drainage, fistulas, diseases of small intestine
 Excessive loss resulting from thiazide diuretics
 Aldosterone excess
 Polyuria

Signs and Symptoms

Physical examination: muscular tremors, hyperactive deep tendon reflexes, confusion and disorientation, tachycardia, hypertension, dysrhythmias, and positive Chvostek's and Trousseau's signs
Laboratory findings: serum magnesium level <0.65 mmol/L

Hypermagnesemia

Renal failure
 Excess oral or parenteral intake of magnesium

Physical examination: acute elevations in magnesium levels: hypoactive deep tendon reflexes, decreased depth and rate of respirations, hypotension, and flushing
Laboratory findings: serum magnesium level >1.05 mmol/L; ECG abnormalities (prolonged QT interval, atrioventricular block)

ECG, Electrocardiogram; GI, gastrointestinal.

► **TABLE 39-4** Fluid Disturbances**Imbalance and Related Causes****Isotonic Imbalances****Fluid Volume Deficit: Water and Electrolytes Lost in Equal or Isotonic Proportions**

GI losses such as diarrhea, vomiting, or drainage from fistulas or tubes
 Loss of plasma or whole blood, such as burns or hemorrhage
 Excessive perspiration
 Fever
 Decreased oral intake of fluids
 Confusion or depression
 Use of diuretics

Signs and Symptoms

Physical examination: postural hypotension, tachycardia, dry mucous membranes, poor skin turgor, thirst, confusion, rapid weight loss, slow vein filling, flat neck veins, lethargy, oliguria (<30 mL/hr), weak pulse
Laboratory findings: urine specific gravity >1.030, increased hematocrit level >50%, and increased BUN level >7.1 mmol/L (see Appendix B) (hemoconcentration)

Fluid Volume Excess: Water and Sodium Retained in Isotonic Proportions

Heart failure
 Renal failure
 Cirrhosis of the liver
 Increased serum aldosterone and steroid levels
 Excessive sodium intake or administration

Physical examination: rapid weight gain, edema (especially in dependent areas), hypertension, polyuria (if renal mechanisms are normal), neck vein distension, increased blood venous pressure, crackles in lungs, confusion
Laboratory findings: decreased hematocrit level <30% and decreased BUN level <3.6 mmol/L (hemodilution)

Osmolar Imbalances**Hyperosmolar Imbalance: Dehydration**

Diabetes insipidus
 Interruption of neurologically driven thirst drive
 Diabetic ketoacidosis
 Osmotic diuresis
 Administration of hypertonic parenteral fluids or tube-feeding formulas

Physical examination: dry and sticky mucous membranes, flushed and dry skin, thirst, elevated body temperature, irritability, convulsions, coma

Laboratory findings: increased serum sodium level >145 mmol/L and increased serum osmolality >300 mmol/kg

Hypo-osmolar Imbalance: Water Excess

Syndrome of inappropriate antidiuretic hormone (SIADH)
 Excess water intake

Physical examination: decreased level of consciousness, convulsions, coma

Laboratory findings: decreased serum sodium level <136 mmol/L and decreased serum osmolality <275 mmol/kg

BUN, Blood urea nitrogen; GI, gastrointestinal.

carbon dioxide is exhaled, and the carbon dioxide concentration decreases. When the PaCO_2 is more than 45 mm Hg, hypoventilation has occurred. As the rate and the depth of respiration decrease, less carbon dioxide is exhaled and more is retained, increasing the concentration of carbon dioxide.

PaO_2 . PaO_2 is the partial pressure of oxygen in arterial blood. It has no primary role in acid-base regulation if it is

within normal limits. A PaO_2 less than 60 mm Hg can lead to anaerobic metabolism, resulting in lactic acid production and metabolic acidosis. A reduction in vital capacity (Martini & Nath, 2009) may contribute to a reduction in PaO_2 in older adults. The normal range is 80 to 100 mm Hg.

Oxygen Saturation. Oxygen saturation is the point at which hemoglobin is saturated by oxygen. Decreasing PaO_2

causes an increase in oxygen dissociation from hemoglobin. Oxygen saturation can be affected by changes in temperature, pH, and PaCO_2 . The normal range is 95% to 99%.

Base Excess. Base excess refers to the buffering systems discussed previously, with a normal range of +2 to -2. Base excess reflects deviations from a serum pH of 7.4 (neutral). Higher values of **base excess** indicate alkalosis. Negative values of base excess indicate acidosis, usually the result of the elimination of too many bicarbonate ions.

Bicarbonate. Serum bicarbonate is excreted or retained by the kidneys to maintain a normal acid-base environment. It is also the principal buffer of the ECFs of the body. A normal pH is maintained with a bicarbonate ratio 20 times that of the fluid concentration of carbonic acid (McCance & Huether, 2010). The normal range is 22 to 26 mmol/L. Less than 22 mmol/L of bicarbonate usually indicates metabolic acidosis, whereas more than 26 mmol/L indicates metabolic alkalosis.

Types of Acid-Base Imbalances

The four primary types of acid-base imbalance are respiratory acidosis, respiratory alkalosis, metabolic acidosis, and metabolic alkalosis (Table 39-5).

Respiratory Acidosis. Respiratory acidosis is marked by an increased PaCO_2 , excess carbonic acid, and an increased hydrogen ion concentration (decreased pH). This occurs when respirations are not effective in excreting carbon dioxide, resulting in an increase in hydrogen concentration. With respiratory acidosis, carbon dioxide crosses the blood-brain barrier, causing neurological changes, such as headaches, irritability, and, ultimately, impaired consciousness. Hypoxemia occurs simultaneously because of respiratory depression, resulting in further neurological impairment. Electrolyte changes such as hyperkalemia and hypercalcemia may accompany the acidosis. The renal system compensates by increasing bicarbonate and eliminating hydrogen ion.

Example: Mr. Butler comes to the emergency department short of breath. The first set of ABGs shows the following: pH = 7.26, PaCO_2 = 55 mm Hg, and bicarbonate = 23 mmol/L. His body has not yet compensated for his respiratory insufficiency. A person with chronic lung disease may present with greater compensation and a pH that is closer to normal.

Respiratory Alkalosis. Respiratory alkalosis is marked by decreased PaCO_2 and increased pH. Respiratory alkalosis can begin outside the respiratory system (e.g., anxiety with hyperventilation) or within the respiratory system (e.g., the initial phase of an asthma attack). Usually, the respiratory system corrects imbalances before compensatory changes are required.

Example: Janet is hyperventilating when she comes into the emergency department. Her ABGs are as follows: pH = 7.52, PaCO_2 = 30 mm Hg, bicarbonate = 24 mmol/L, and base excess = 2.5 mmol/L. Her kidneys have not had time to compensate and lower the bicarbonate level.

Metabolic Acidosis. Metabolic acidosis results from a decrease in serum bicarbonate or the production of organic or fixed acids. An analysis of serum electrolytes to detect an anion gap may be helpful in attempting to identify the cause of the metabolic acidosis. An **anion gap** reflects unmeasurable anions present in plasma and is calculated by subtracting the sum of chloride and bicarbonate from the amount of plasma sodium concentration. Compensation for metabolic acidosis initially involves an increase in respiratory rate and depth to eliminate

carbon dioxide. If not quickly resolved, renal mechanisms are stimulated to increase hydrogen ion excretion, and to generate and release bicarbonate into the ECF.

Example: Ms. Jane Smith is admitted to hospital after having run her first marathon. Her electrolytes are as follows: sodium = 131 mmol/L, bicarbonate = 9 mmol/L, and chloride = 86 mmol/L. You would calculate the anion gap as follows: $\text{Na} - (\text{HCO}_3^- + \text{Cl}^-) = 131 - (9 + 86) = 36$ mmol/L. The normal anion gap is less than 16 mmol/L (so her anion gap is high). Ms. Smith receives a diagnosis of lactic acidosis related to tissue hypoxia.

Diabetic ketoacidosis (DKA) is characterized by hyperglycemia, high ketones, and metabolic acidosis. This diabetic emergency is caused by a total lack of insulin, in type 1 diabetes, causing severely elevated glucose levels. The body responds to the glucose deficit inside the cells by mobilizing fats, a process that results in increased ketone bodies. Together, these metabolic processes cause osmotic diuresis, acidosis, and hyperkalemia. Patients with type 2 diabetes are also at risk of developing metabolic acidosis from severe hyperglycemia, although the acidosis develops more slowly and is not associated with ketosis. You respond to these hyperglycemic emergencies by administering insulin and intravenous fluids beginning with 0.9% saline (Kisiel & Marsons, 2009, p. 1097). Frequent monitoring of electrolytes, fluid balance, glucose, and ABGs is important in the treatment of DKA.

Metabolic Alkalosis. Metabolic alkalosis is marked by the heavy loss of acid from the body or by increased levels of bicarbonate. The most common causes are vomiting and gastric suction, as well as potassium deficiency, hyperaldosteronism, and diuretic therapy (McCance & Huether, 2010). The body attempts to compensate by increasing the excretion of bicarbonate and decreasing the rate and the depth of respirations. Symptoms associated with metabolic alkalosis are depressed respirations and tingling of the fingers and dizziness related to secondary low calcium (Day et al., 2010). In serious metabolic alkalosis, cardiac arrhythmias can occur.

Example: Mr. Jones comes into the clinic with persistent vomiting. His ABGs are as follows: pH = 7.63, bicarbonate = 45 mmol/L, PaCO_2 = 48 mm Hg, and base excess = 16 mmol/L. He is in metabolic alkalosis.

Knowledge Base of Nursing Practice

The essential functions of fluid, electrolyte, and acid-base balances are important aspects of the scientific knowledge base of nursing practice. In all areas of nursing practice, nurses attend to the relationship between healthy water and human health (Davidhizar et al., 2004). Regardless of the area of practice, all nurses will be involved in assessment, planning, and interventions in relation to water, electrolytes, and factors that influence acid-base balance. Certain patients are particularly vulnerable to imbalances, including infants, older adults, and the severely ill. Patients who are disoriented or immobile are also vulnerable to imbalances because they cannot respond independently to early symptoms. If untreated, over time, the body can no longer maintain fluid and electrolyte or acid-base balances adequately, and the patient's health becomes compromised. Prolonged or severe compromises may lead to irreversible chronic health problems (Box 39-2). Good nursing care involves informed assessment in relation to fluid, electrolyte, and acid-base balances.

► TABLE 39-5 Acid-Base Imbalances

Imbalance and Related Causes**Respiratory Acidosis****Hypoventilation Resulting From Primary Respiratory Problems**

Atelectasis pneumonia
Cystic fibrosis
Respiratory failure
Airway obstruction
Chest wall injury

Hypoventilation Resulting From Factors Outside the Respiratory System

Drug overdose with a respiratory depressant
Paralysis of respiratory muscles caused by various neurological alterations
Head injury
Obesity

Signs and Symptoms

Physical examination: confusion, dizziness, lethargy, headache, ventricular dysrhythmias, warm and flushed skin, muscular twitching, convulsions, and coma

Laboratory findings: arterial blood gas alterations: pH <7.35, PaCO₂ >45 mm Hg, PaO₂ <80 mm Hg, and bicarbonate level normal (if uncompensated) or >26 mmol/L (if compensated)

Physical examination: confusion, dizziness, lethargy, headache, ventricular dysrhythmias, warm and flushed skin, muscular twitching, convulsions, and coma

Laboratory findings: arterial blood gas alterations: pH <7.35, PaCO₂ >45 mm Hg, PaO₂ <80 mm Hg, and bicarbonate level normal (if uncompensated) or >26 mmol/L (if compensated)

Respiratory Alkalosis**Hyperventilation Resulting From Primary Respiratory Problems**

Asthma
Pneumonia
Inappropriate mechanical ventilator settings

Physical examination: dizziness, confusion, dysrhythmias, tachypnea, numbness and tingling of extremities, convulsions, and coma

Laboratory findings: arterial blood gas alterations: pH >7.45, PaCO₂ <35 mm Hg, PaO₂ normal, and bicarbonate level normal (if short-lived or uncompensated) or <22 mmol/L (if compensated)

Hyperventilation Resulting From Factors Outside the Respiratory System

Anxiety
Hypermetabolic states (fever, exercise)
Disorders of the central nervous system (head injuries, infections)
Salicylate overdose

Physical examination: dizziness, confusion, dysrhythmias, tachypnea, numbness and tingling of extremities

Laboratory findings: arterial blood gas alterations: pH >7.45, PaCO₂ <35 mm Hg, PaO₂ normal, and bicarbonate level normal (if short-lived or uncompensated)

Metabolic Acidosis**High Anion Gap**

Starvation
Diabetic ketoacidosis
Renal failure
Lactic acidosis from heavy exercise
Use of drugs (e.g., methanol, ethanol, formic acid, paraldehyde, aspirin)

Physical examination: headache, lethargy, confusion, dysrhythmias, tachypnea with deep respirations, abdominal cramps, and flushed skin

Laboratory findings: arterial blood gas alterations: pH <7.35, PaCO₂ normal (if uncompensated) or <35 mm Hg (if compensated), PaO₂ normal or increased with rapid, deep respirations, bicarbonate level <22 mmol/L, and oxygen saturation normal

Normal Anion Gap

Renal tubular acidosis
Diarrhea

Physical examination: headache, lethargy, confusion, dysrhythmias, tachypnea with deep respirations, abdominal cramps, and flushed skin

Laboratory findings: arterial blood gas alterations: pH <7.35, PaCO₂ normal (if uncompensated) or <35 mm Hg (if compensated), PaO₂ normal or increased with rapid, deep respirations, anion gap (difference between positive ions and negative ions) of greater than 12 mmol/L

Metabolic Alkalosis

Excessive vomiting
Prolonged gastric suctioning
Hypokalemia or hypercalcemia
Excess aldosterone
Use of drugs (steroids, sodium bicarbonate, diuretics)

Physical examination: dizziness; dysrhythmias; numbness and tingling of fingers, toes, and circumoral region; muscle cramps; tetany

Laboratory findings: arterial blood gas alterations: pH >7.45, PaCO₂ normal (if uncompensated) or >45 mm Hg (if compensated), PaO₂ normal, and bicarbonate level >26 mmol/L

PaCO₂, Partial pressure of carbon dioxide in arterial blood; PaO₂, partial pressure of oxygen in arterial blood; pH, measurement of the acidity or alkalinity of a fluid.

Gastrointestinal Losses

Gastroenteritis
Nasogastric suctioning
Fistulas

Knowledge

- Physiology of fluid, electrolyte, and acid-base balances
- Disease and other alterations of fluid, electrolyte, and acid-base balances
- Role of developmental stage in fluid, electrolyte, and acid-base balances
- Role of medications in fluid balance
- Influence common risk factors have on fluid and electrolyte balances

Experience

- Caring for patients with impaired fluid balance
- Personal experience with dehydration secondary to high environmental temperature, prolonged physical activity, mild gastrointestinal upset

Assessment

- Identify recurring and present symptoms associated with the patient's fluid alteration
- Determine how the patient's underlying disease affects daily function
- Determine the patient's medication use
- Assess the patient's physical examination findings
- Assess the patient's laboratory results

Standards

- Apply intellectual standards of accuracy, relevancy, and significance to obtaining a health history of the patient with fluid alterations
- Apply Infusion Nurses Society (INS) standards for assessing fluid balance (INS, 2006)
- Consider laboratory standards for normal electrolyte values

Qualities

- Use discipline to obtain complete and correct assessment data regarding patient's fluid status
- Be responsible for collecting appropriate specimens for diagnostic and laboratory tests related to the patient's fluid balance

Critical Thinking

Successful critical thinking requires a synthesis of knowledge, experience, information gathered from patients, critical thinking qualities, and intellectual and professional standards. You must use clinical judgments to anticipate the information necessary, analyze the data, and make decisions regarding patient care. During assessment (Figure 39-7), you must consider all elements that contribute to making appropriate nursing diagnoses.

To understand how fluid, electrolyte, and acid-base imbalances affect the patient, you must integrate knowledge of physiology, pathophysiology, and pharmacology with previous experiences and information gathered from the patient. Professional standards provide valuable guidelines for comprehensive assessment and intelligent planning and intervention.

Nursing Process

◆ Assessment

Patient care begins with informed assessment, including the status of the patient's fluid, electrolyte, and acid-base balances. Assessment is informed by knowledge of risk factors, physiology, and developmental considerations. By gathering

data through a health history and physical examination, you will identify patients at risk and then identify all appropriate nursing diagnoses.

Health History

The nursing assessment begins with a nursing health history, which is designed to reveal any risk factors or preexisting conditions that may cause or contribute to a disturbance of fluid, electrolyte, and acid-base balances (Box 39-3).

Age. First, consider the patient's age. An infant's proportion of total body water, approximately 75%, is greater than that of children or adults. Infants are at a greater risk for **fluid volume deficit (FVD)** and hyperosmolar imbalance because body water loss is proportionately greater per kilogram of weight, and therefore, they have smaller reserves.

Children ages 2 through 12 years have less stable regulatory responses to imbalance and in childhood illnesses tend to have less tolerance for large changes. Children frequently respond to illnesses with fevers of higher temperatures and longer duration than those of adults, increasing their insensible water loss. Adolescents have increased metabolic processes and water production because of the major rapid changes that occur during puberty. Adolescent girls experience changes in

Figure 39-7 Critical thinking model for assessment of fluid, electrolyte, and acid-base balances.

► BOX 39-3 Nursing Assessment Questions

Nature of the Problem

- Are you currently under the care of a health care provider for management of any ongoing health problems, such as kidney or heart disease, diabetes, or blood pressure problems?
- Describe any new problems, such as vomiting, diarrhea, or a surgical procedure.
- Do you regularly take any medications, such as antacids, diuretics, or other blood pressure medication? Do you use salt substitutes or calcium or potassium supplements?

Signs and Symptoms

- In the past several weeks, have you lost or gained any weight?
- Do you feel thirsty, have a dry mouth or skin, or notice a lack of tears?
- Have you noticed a change in your urine output: decreased volume, dark colour, or concentrated appearance?
- Have you had any recent problems with vomiting or diarrhea? If so, for how long?
- Are you experiencing any problems with swelling of your hands, feet, ankles, or lower legs?
- Do you have problems breathing when you lie down at night?
- Have you noticed any dizziness, weakness, cramps, or unusual sensations, such as tingling?

Severity

- How many times a day do you urinate?
- Do you continue to feel thirsty no matter how much fluid you drink?
- Are you experiencing these symptoms more at night than in the morning?
- Are you having difficulty concentrating or do you feel confused?
- How does this compare with what is normal or usual for you?

Predisposing Factors

- How much do you usually drink every day? What type of fluids do you drink?
- Describe your normal diet. Do you frequently eat processed, canned, or frozen foods? Are you following a weight loss program?
- Have you had any recent changes in your appetite? Have you noticed any changes in the taste of your food?

Effect on the Patient

- How have these symptoms affected you?
- Are you losing sleep, feeling irritable, or having difficulty performing your usual daily tasks?

fluid balance with the hormonal changes associated with the menstrual cycle.

Because of the growing aging population, nurses need to be able to identify the risk factors for fluid and electrolyte imbalances and work to prevent them (Box 39-4). Aging has a significant impact on fluid, electrolyte, and acid-base balances and on compensatory mechanisms. Total body water proportion gradually declines with age; however, this varies significantly with gender, height, and weight (Wotton et al., 2008). With normal aging, the glomerular filtration rate is reduced, along with the number and functional capacity of nephrons. Changes in the skin and skeletal and muscle mass result in the need for a higher water intake, although older adults have a decreased thirst sensation. The reduction in taste may limit the

* BOX 39-4

EVIDENCE-INFORMED PRACTICE GUIDELINE

Preventing Dehydration in Older Adults

- Calculating fluid requirements should take into consideration individual characteristics including weight, gender, and co-morbidities, such as renal and cardiac disease.
- Identify risk factors for each older adult from the following: >70 years, female, high or low BMI, recent hospitalization, new admission to residential care, situations causing increased insensible loss, decreased access or ability to request fluids, and situations causing decreased intake, such as swallowing disorder, decreased sentence, in addition to many physiological factors. Previous malnutrition, dehydration, polypharmacy, and >3 medical conditions are significant risk factors.
- Maintain fluid intake with fluid monitoring by professional caregivers in residential care settings.
- Personal knowledge of older adults is key to early identification of risk factors and developing dehydration.
- Assessment of hydration status should include physiological measures (urine specific gravity, urine colour, blood pressure, pulse, and respiration), as well as observed intake patterns and treatments.
- Evaluate acute losses such as vomiting, medical issues such as diabetes or malnutrition, use of medications such as diuretics, cognitive level, and functional status.
- Acute management requires prompt response to prevent hypovolemia.
- Ongoing management consists of daily fluid goals, comparing current intake with physiological needs, and easy access to fluids. Balancing caffeinated and alcoholic beverages with other fluids is important.
- Documentation should include hydration, eating habits, weight, vital signs, and fluid preferences.

Adapted from Wotton, K., Crannitch, K., & Munt, R. (2008). Prevalence, risk factors and strategies to prevent dehydration in older adults. *Contemporary Nurse: A Journal for the Australian Nursing Profession*, 31(1), 44–56.

amount of oral fluids consumed. Older adults have a reduction in aldosterone, which increases sodium excretion and may result in hyponatremia. Because older adults are more susceptible to dehydration and have a higher rate of mortality from dehydration, early detection of infection and disorders in fluid balance is very important (Wotton et al., 2008).

Reduced respiratory lung capacity impairs the ability of older adults to compensate for acid-base imbalances and maintain oxygen requirements. With increased age, patients are at risk for disorders of other body systems, including the cardiovascular, renal, and endocrine systems. In addition, older adults have a decreased ability to excrete medications.

Environmental Factors. You should also include certain environmental factors in the health history. Patients who have participated in vigorous exercise or are exposed to temperature extremes may have clinical signs of fluid and electrolyte alterations. Exposure to environmental temperatures exceeding 28°C to 30°C results in excessive sweating with weight loss. A body weight loss over 7% decreases the ability of the cooling mechanism to conserve water. Loss of fluid from sweating varies and can reach up to 1 to 3 L/hour (McCance

& Huether, 2010). Inadequate fluid and electrolyte replacement can lead to imbalances.

Diet. A patient's current dietary history is an important component of nursing assessment. Dietary intake of fluids, salt, potassium, calcium, magnesium, carbohydrates, fats, and protein helps maintain normal fluid, electrolyte, and acid-base homeostasis. Recent changes in appetite or the ability to chew and swallow can affect nutritional status and hydration. When nutritional intake is inadequate, the body tries to preserve its protein stores by breaking down glycogen and fat stores. When excess free fatty acids are released, metabolic acidosis can occur because the liver converts free fatty acids to ketones, which are strong acids. With high-protein diets, ketosis can also occur. After fat and carbohydrate resources are depleted, the body begins to destroy protein stores. Hypoalbuminemia occurs with lack of amino acids in the diet and with liver dysfunction. In hypoalbuminemia, the serum colloid osmotic pressure is decreased, allowing fluid to shift from the circulating plasma to the interstitial fluid spaces.

Lifestyle. Lifestyle factors should also be included in the patient's health history. Preexisting medical risks, such as a history of smoking or alcohol consumption, can further impair the patient's ability to adapt to fluid, electrolyte, and acid-base alterations. For example, the excessive use of alcohol can ultimately cause respiratory depression, which can result in respiratory acidosis.

Medication. A final category to include in the nursing assessment is a history of prescription medication use (Box 39-5). If the assessment reveals a medication that is likely to cause an electrolyte or acid-base disorder, you will need to examine pertinent laboratory values closely. You will assess the patient's knowledge of side effects and adherence to medication schedules. You will also explore the use of over-the-counter medications and consider their influence on homeostasis.

Prior Medical History

Acute Illness. Recent surgery, head and chest trauma, sepsis, shock, and second- or third-degree burns are conditions

that place patients at high risk for fluid, electrolyte, and acid-base alterations. The patient continues to be at risk during the acute phase until the underlying process is resolved. For example, the stress response of surgery may cause fluid shifts postoperatively when aldosterone, glucocorticoids, and ADH are increasingly secreted, causing sodium and chloride retention, potassium excretion, and decreased urinary output.

Surgery. The more extensive the surgery and fluid loss are during the surgical procedure, the greater the body's response is to the surgical trauma. After surgery, patients can exhibit many acid-base changes. The patient who is reluctant to breathe deeply and cough may develop respiratory acidosis as a result of retained PaCO_2 . The patient with nasogastric suction may develop metabolic alkalosis as a result of the loss of gastric acid, fluids, and electrolytes.

Burns. The greater the body surface burned, the greater the fluid loss. The burned patient can lose body fluids by many routes. Plasma leaves the intravascular space and becomes trapped as edema. This is also called the plasma-to-interstitial fluid shift. It is accompanied by a loss of serum proteins. Plasma and interstitial fluids are also lost as burn exudate. Water vapour and heat are lost in proportion to the amount of skin that is burned away, increasing insensible losses. Blood leaks from damaged capillaries, adding to the loss of intravascular fluid volume. Sodium and water shift into the cells, further compromising ECF volume (Day et al., 2010).

Respiratory Disorders. Many alterations in respiratory function predispose the patient to respiratory acidosis. For example, pneumonia or sedative overdose interfere with the elimination of carbon dioxide due to hypoventilation. As the carbon dioxide continues to build up in the bloodstream, the body's compensatory mechanisms can no longer adapt, and the pH decreases. Likewise, hyperventilation that occurs with conditions such as fever or anxiety can cause respiratory alkalosis when too much carbon dioxide is expelled with the increased respiratory rate.

Gastrointestinal Disturbances. Gastroenteritis and nasogastric suctioning result in a loss of fluid, potassium, and chloride ions. Hydrogen ions are also lost, resulting in metabolic alkalosis. Timely education of infant and child caregivers is necessary to prevent dehydration when the infant or child is experiencing diarrhea. Gastrointestinal fistulas can also result in a loss of potassium, resulting in an increased risk for hypokalemia and acid-base imbalance.

Head Injury. Head injury can result in cerebral edema. Occasionally, this edema creates pressure on the pituitary gland, and, as a result, ADH secretion is changed. Diabetes insipidus occurs when too little ADH is secreted and the patient excretes large volumes of diluted urine with a low specific gravity. Syndrome of inappropriate antidiuretic hormone (SIADH) results in water intoxication characterized by fluid volume expansion and hyponatremia, as well as hypotonicity of fluids as a result of high urine osmolality and low serum osmolality (McCance & Huether, 2010).

Chronic Illness. Chronic disease (e.g., cancer, heart failure, or renal disease) can create fluid, electrolyte, and acid-base imbalances. The normal course of the patient's chronic disease is important in order to understand how fluid, electrolyte, and acid-base status may be affected.

Cancer. The types of fluid and electrolyte imbalances that are observed in a patient with cancer depend on the type and progression of the cancer. The potential electrolyte imbalances result from anatomical distortion and functional impairment

► BOX 39-5

Medications That Cause Fluid, Electrolyte, and Acid-Base Disturbances

- Diuretics: Metabolic alkalosis, hyperkalemia, and hypokalemia
- Steroids: Metabolic alkalosis
- Potassium supplements: Gastrointestinal disturbances, including intestinal and gastric ulcers and diarrhea
- Respiratory centre depressants (e.g., opioid analgesics): Decreased rate and depth of respirations, resulting in respiratory acidosis
- Antibiotics: Nephrotoxicity (e.g., vancomycin, methicillin, aminoglycosides); hyperkalemia or hyponatremia (e.g., azlocillin, carbenicillin, piperacillin, ticarcillin, ampicillin sodium-sulbactam sodium [Unasyn])
- Calcium carbonate (Tums): Mild metabolic alkalosis with nausea and vomiting
- Magnesium hydroxide (Milk of Magnesia): Hypokalemia
- Nonsteroidal anti-inflammatory drugs: Nephrotoxicity

Data from McKenry, L., Tessier, E., & Hogan, M. A. (2006). *Mosby's pharmacology in nursing* (22nd ed.). St Louis, MO: Mosby.

from tumour growth, or tumour-related metabolic and endocrine abnormalities. In addition, patients with cancer are at risk for fluid and electrolyte imbalances related to the side effects (e.g., diarrhea and anorexia; stomatitis) of their chemotherapeutic and radiological treatments.

Cardiovascular Disease. In the patient with cardiovascular disease, diminished cardiac output reduces kidney perfusion, causing the patient to experience a decrease in urinary output. The patient will retain sodium and water, resulting in circulatory overload, and is at risk of developing pulmonary edema. Fluid and electrolyte imbalances associated with heart disease can be controlled with medications and with fluid and sodium restrictions.

Renal Disorders. Kidney disease alters fluid and electrolyte balances by the abnormal retention of sodium, chloride, potassium, and water in the extracellular compartment. The plasma levels of metabolic waste products such as urea and creatinine are elevated because the kidneys are unable to filter and excrete the waste products of cellular metabolism. This elevation is toxic to cellular processes. Metabolic acidosis results when hydrogen ions are retained because of decreased renal function. Because of the renal disorder, the usual renal compensatory mechanisms, such as bicarbonate reabsorption, are not available; therefore, the body's ability to restore normal acid-base balance is limited.

The severity of fluid and electrolyte imbalance is proportional to the degree of renal failure. Acute renal failure is reversible. Although chronic kidney disease is progressive, the patient may be treated successfully with dietary control of protein and salt intake, diuretic medications, and fluid restrictions. In later stages, treatment with dialysis, transplantation, or both may be required.

Gastrointestinal Disorders. Chronic gastrointestinal (GI) disorders can have a serious impact on fluid, electrolyte, and acid-base balances. Inflammatory bowel diseases, such as ulcerative colitis, regional enteritis, and celiac disease, are relatively common (Day et al., 2010). Patients with liver failure may have a number of imbalances, including metabolic acidosis, ECF shifts in the case of ascites, and electrolyte disturbances. Key GI assessments include the length of the illness, the presence of exacerbations in the case of inflammatory bowel disease, and the type of treatment currently being administered. Determine whether the patient has a history of acute illnesses such as diarrhea or vomiting. Any condition that results in the loss of gastrointestinal fluids predisposes the patient to the development of dehydration and a variety of electrolyte disturbances.

Human Immunodeficiency Virus (HIV) and Acquired Immune Deficiency Syndrome (AIDS). The types of fluid and electrolyte imbalances that are observed in patients with HIV and AIDS depend on the stage of the disease and manifestations of the illness, complications (e.g., nephropathy, malignancy, and opportunistic infections), and the side effects of antiretroviral therapy. Electrolyte and acid-base imbalances can occur as a result of anorexia, nausea, vomiting, diarrhea, and malignancies. Treatment should focus on improving food and fluid intake, providing comfort measures, and addressing the cause of the imbalance.

Physical Assessment

A thorough physical examination (see Chapter 31) is necessary because fluid and electrolyte imbalances or acid-base disturbances can affect all body systems. When conducting a

physical examination, incorporate knowledge regarding the signs and symptoms of fluid, electrolyte, and acid-base imbalances; disease processes that may affect these balances; developmental considerations; and common risk factors. For example, an examination of the oral cavity may reveal signs of dehydration. Table 39-6 summarizes possible physical findings for patients with fluid, electrolyte, and acid-base imbalances.

Measuring Fluid Intake and Output. Assessing fluid balance involves knowledge of normal fluid requirements and accurate measurement techniques (Chapelhow & Crouch, 2007). Measuring and recording all intake and output during a 24-hour period is one key component of patient assessment. This is particularly important for patients after a procedure or if febrile, on restricted fluids, or receiving diuretic or intravenous therapy. Recognition of trends in intake and output is also important.

Daily weight is considered the most accurate means to evaluate fluid balance (Day et al., 2010). Weigh the patient at the same time each day with the same scale after the patient voids. Calibrate the scale routinely. The patient should wear the same clothes (or clothes that weigh the same); if you are using a bed scale, use the same number of sheets on the scale with each weighing.

Intake includes all liquids taken by mouth (e.g., gelatin, ice cream, soup, juice, and water) or through nasogastric or jejunostomy feeding tubes, intravenous fluids (including both continuous and intermittent intravenous fluids), and blood or its components. A patient receiving tube feedings may receive numerous liquid medications and water may be used to flush the tube. Over a 24-hour period, these liquids can amount to significant intake and should always be recorded on the intake and output record. Output includes urine, diarrhea, vomitus, gastric suction, and drainage from postsurgical wounds or other tubes (see Chapter 48). Daily intake should equal output plus 500 mL (to cover for insensible fluid losses).

To measure output, ambulatory patients are instructed to save their urine in a calibrated receptacle that attaches to the rim of the toilet bowl. When a patient has an in-dwelling Foley catheter, drainage tube, or suction, output is recorded at predetermined times depending on the patient's condition and physicians' orders. Patient and family cooperation is essential for accurate intake and output measurements. Teach the patient and the family the purpose of the measurements, including oral intake.

Recording intake and output is essential for obtaining an accurate database. This information helps maintain an ongoing evaluation of the patient's hydration status to prevent severe imbalances. In the hospital, forms for recording intake and output are attached to the bedside, chart, or room door (Figure 39-8). The 24-hour total is calculated as directed by agency policy. You may delegate intake and output recording to unregulated care providers with competent skills in measurement and calculation. Estimation is not acceptable.

Laboratory Studies. Review laboratory data, including serum and urinary electrolyte levels, hematocrit, blood creatinine level, blood urea nitrogen (BUN) levels, urine specific gravity, and ABG readings (Box 39-6). Serum electrolyte levels are measured to determine the hydration status, the electrolyte concentration of the blood plasma, and acid-base balance. The frequency with which these electrolyte levels are measured depends on the severity of the patient's illness. Serum electrolyte tests are routinely performed on any patient entering a hospital to screen for alterations and to serve as a baseline for

future comparisons. Serum and urine osmolality are also used to assess fluid balance (Goertz, 2006). The normal range for serum osmolality is 285 to 295 mmol/kg. With dehydration, the serum osmolality will be higher than normal.

Arterial Blood Gases. To determine ABG levels, a sample of blood from an artery must be taken to assess the patient's acid-base status and the adequacy of ventilation and oxygenation. Arterial blood is drawn from a peripheral artery (usually the radial artery) or from an arterial line inserted by a physician. In some agencies, nurses are responsible for radial

artery punctures. You may also need to assist in the sampling process and care for the patient after the procedure. After the specimen is obtained, care is taken to prevent air from entering the syringe because this will affect the ABG analysis. The syringe should be transported to the laboratory immediately. In the event of a delay of more than 20 minutes, the syringe is submerged in crushed ice for transport to the laboratory to reduce the metabolism of cells. Apply pressure to the puncture site for at least five minutes to reduce the risk of hematoma formation. Reassess the pulse after pressure has been removed.

PaCO_2 : 35 mm Hg

PaO_2 : Normal

Oxygen saturation: Normal

Bicarbonate: 22 mmol/L

Potassium: 3.5 mmol/L

Respiratory Acidosis

pH: 7.35

PaCO_2 : 45 mm Hg

PaO_2 : Normal or <80 mm Hg, depending on cause of acidosis

Oxygen saturation: Normal or 95%, depending on cause of acidosis

Bicarbonate: Normal if early respiratory acidosis or >26 mmol/L if kidneys are compensating

Potassium: 5.0 mmol/L

BUN, Blood urea nitrogen; *ECF*, extracellular fluid; PaCO_2 , partial pressure of carbon dioxide in arterial blood; PaO_2 , partial pressure of oxygen in arterial blood; *pH*, measurement of acidity or alkalinity of a fluid.

Patient Expectations

Often the patient's fluid, electrolyte, or acid-base disturbance is so serious that it prevents a review of patient expectations. However, if a patient is alert enough to discuss care, explore short-term needs (e.g., provision of comfort from nausea) and long-term needs (e.g., understanding how to prevent alterations from occurring in the future). You may also explore patient expectations with family and supportive friends. Strengthen the patient's trust through a competent response to sudden changes in condition and through communication with patients and/or family members.

► BOX 39-7

NURSING DIAGNOSTIC PROCESS**Deficient Fluid Volume****Assessment Activities**

Assess blood pressure and pulse
Obtain daily weight measurements
Observe volume of urine output and measure intake and specific gravity
Assess skin turgor
Ask if patient is thirsty or weak
Inspect mucous membranes for degree of moisture

Defining Characteristics

Patient is hypotensive, with increased heart rate
Patient experiences sudden weight loss
Decreased volume of output in comparison to intake; increased urine specific gravity is present
Inelastic skin turgor noted
Patient verbalizes thirst and weakness
Dry mucous membranes are noted

❖Nursing Diagnosis

When caring for patients with suspected fluid, electrolyte, and acid-base imbalances, it is particularly important to use critical thinking to formulate nursing diagnoses. The assessment data that establish the risk for or the actual presence of a nursing diagnosis in these areas may be subtle, and patterns and trends emerge only when you conscientiously assess for them. You must keep in mind that many body systems may be involved. Clustering of defining characteristics will lead you to select the appropriate diagnoses. For example, the nursing diagnosis *deficient fluid volume* is developed in Box 39-7.

An important part of formulating nursing diagnoses is identifying the relevant causative or related factor. The nursing interventions are chosen to treat or modify the related factor. *Deficient fluid volume related to loss of gastrointestinal fluids via vomiting* necessitates therapies different from those needed for *deficient fluid volume related to elevated body temperature*.

Possible nursing diagnoses for patients with fluid, electrolyte, and acid-base alterations are the following:

- *Actual or risk of deficient fluid volume*
- *Actual or risk of excess fluid volume*
- *Decreased cardiac output*
- *Impaired breathing pattern*
- *Impaired gas exchange*
- *Impaired tissue perfusion*
- *Acute confusion*
- *Impaired oral mucous membrane*
- *Actual or risk of impaired skin integrity*
- *Impaired mobility*
- *Ineffective therapeutic regimen management*
- *Impaired tissue integrity*
- *Deficient knowledge regarding disease management*

❖Planning

During the planning process, use critical thinking to synthesize information from multiple sources and to ensure that the patient's care plan integrates both scientific and nursing knowledge, your knowledge of the individual, and the patient's expectations (Figure 39-9).

Goals and Outcomes

Develop an individual care plan for the nursing diagnoses (see Box 39-7 and Box 39-8). Goals or expectations for care

Figure 39-9 Critical thinking model for planning fluid, electrolyte, and acid-base balances.

set by you and the patient should be individualized and realistic, with measurable outcomes. For example, if the goal is to achieve and maintain homeostasis, the following related outcomes might be established: *The patient will have normal fluid and electrolyte balance at discharge:*

- The patient will be free of complications associated with the intravenous therapy.
- The patient will demonstrate fluid balance by moist, mucous membranes and good skin turgor.
- The patient will have serum electrolytes within the normal range within 48 hours.

Setting Priorities

The patient's clinical condition will determine which diagnosis takes the greatest priority. Many nursing diagnoses in the area of fluid, electrolyte, and acid-base balances are of highest priority because the consequences for the patient can be serious or even life-threatening. For example, in the concept map for the patient with gastroenteritis and dehydration (Figure 39-10), nausea and diarrhea have caused a fluid volume deficit and electrolyte imbalances. Without treating the cause, the fluid, electrolyte, and acid-base imbalances will progress.

Consultation with the patient's physician may assist in setting realistic time frames for the goals of care, particularly when the patient's physiological status is unstable. During planning, collaborate as much as possible with the patient, family, and other members of the health care team. The family can be particularly helpful in identifying subtle changes in a patient's behaviour associated with imbalances (e.g., anxiety, confusion, or irritability).

Continuity of Care

For patients with acute disturbances, discharge planning must begin early. You must ensure that care can continue in the home or long-term care setting with few disruptions. For example, when a patient is discharged on intravenous therapy, you must determine the knowledge and skills of the person who is to assume caregiving responsibilities and make a referral for home intravenous therapy as soon as possible. You must also collaborate closely with other members of the health care team, such as the dietitian, pharmacist, and physician. In consultation with a dietitian, you can recommend foods to increase intake of certain electrolytes or reduce intake as necessary (see Chapter 42). The pharmacist can help identify medications likely to cause electrolyte or acid-base disturbances and describe possible side effects of the patient's prescribed drugs. The physician directs the treatment of any fluid, electrolyte, or acid-base alteration.

Implementation

Health Promotion

Health promotion activities in the area of fluid, electrolyte, and acid-base imbalances include patient education regarding fluid and electrolyte requirements, promotion of healthy environments affecting hydration, and advocating for secure access to safe water as a universal need and human right (International Council of Nurses [ICN], 2008).

Patients and caregivers need to recognize risk factors for imbalances and implement appropriate preventive measures. For example, parents of infants need to understand that gastrointestinal losses can quickly lead to serious imbalances. When an infant is vomiting or has diarrhea, the parent must recognize the risk and promptly seek health care to restore normal balance. Even a healthy adult is at risk for developing imbalances when subjected to high temperatures. Advise patients to increase water intake, maintain adequate ventilation, and refrain from excessive activity during heat waves. Refer to Box 39-4 for guidelines for preventing dehydration in older adults.

All patients with a chronic health alteration are at risk for developing changes in their fluid, electrolyte, and acid-base balances. They need to understand their own risk factors and the measures to be taken to avoid imbalances. For example, patients with renal failure must avoid excess intake of fluid, sodium, potassium, and phosphorus. Through diet education, these patients learn the types of foods to avoid and the suitable volume of fluid they are permitted daily (Box 39-9; see Chapter 42). Patients with chronic health conditions need to be made aware of early signs and symptoms of fluid, electrolyte, and acid-base imbalances. A patient with heart disease should be instructed to obtain an accurate body weight each day at approximately the same time and to inform the health care provider of significant changes in weight from one day to another. Increase in weight, shortness of breath,

► BOX 39-8 NURSING CARE PLAN

Fluid Volume Deficit

Assessment

Mrs. Hilda Topping is a 72-year-old who presented to her health care provider this morning concerned about two days of vomiting and diarrhea. She initially thought that she had food poisoning, but the symptoms have not abated, and she now feels very weak and dizzy and has a headache. After an initial assessment, Mrs. Topping's physician admits her to a medical unit with a diagnosis of dehydration secondary to gastroenteritis. She had baseline blood work and an abdominal X-ray to rule out bowel obstruction. The significant findings are an elevated hematocrit at 56%, elevated hemoglobin (160 g/L), hypernatremia (sodium 146 mmol/L), hypokalemia (potassium 3.2 mmol/L), and elevated blood urea nitrogen (BUN) (10 mmol/L) and creatinine (90 mmol/L). Mrs. Topping's vital signs on admission were as follows: B/P 80/66, P 110, R 18/min, T 37.8, O₂ saturation 95% on room air.

Assessment Activities

Ask Mrs. Topping to describe her activities before onset of her symptoms, including any recent travel.

Findings and Defining Characteristics

Mrs. Topping states that she has been caring for her great-grandchildren for the past week during their school break. She is aware that one of the children had a "tummy upset." In addition, she reports that she had taken them to a fast-food restaurant for a treat. She has not been travelling.

Have Mrs. Topping describe her symptoms, including the frequency and quality of her bowel movements and emesis.

Mrs. Topping describes up to 10 liquid stools per day, accompanied by waves of nausea. With nausea, she often vomits bile-coloured liquid in very small amounts. She had taken a cup of tea twice over the previous day but was "unable to keep [it] down." She describes acute cramping pain.

Assess her vital signs, bowel sounds, skin turgor, and the characteristics of her urine and output every four hours.

She has increased bowel sounds throughout her abdomen. Her mucous membranes are dry, her tongue is coated, and her lips are cracked. Her urine is dark amber, and she voided only 100 mL on request for a sample.

Evaluate her ABGs.

ABG results show metabolic alkalosis. Her pH = 7.5, bicarbonate = 45 mmol/L, PaCO₂ = 48 mm Hg, and base excess = 11 mmol/L.

Nursing Diagnosis: FVD from excessive loss of fluid and electrolytes through increased gastrointestinal loss.

Planning

Goals (Nursing Outcomes Classification)*

The patient will maintain fluid balance as evidenced by balanced intake and output, maintenance of adequate hydration, and absence of manifestations of fluid volume deficit.

Expected Outcomes

Electrolyte and Acid-Base Balances

Patient's vital signs will return to normal and remain stable. No orthostatic blood pressure evident.

ABG levels will be within normal limits in 24 hours.

Electrolyte values and any other abnormal blood work values will return to normal within 24 hours.

Fluid Balance

Urinary output will increase to 1300–1500 mL over the next 23 hours.

Patient's fluid volume will return to normal and remain within normal limits throughout hospital stay.

Mucous membranes will remain moist.

The patient will not develop late signs of hypovolemia.

Renal damage will be prevented and the patient will not develop signs acute renal failure or shock (cyanosis, cold clammy skin, weak thready pulse, confusion, and oliguria).

Abdominal Pain

The patient will report relief of abdominal pain.

Patient will have a reduction in abdominal cramping within two hours.

Interventions (Nursing Interventions Classification)*

Fluid, Electrolyte, and Acid-Base Management

Initiate and administer intravenous solution per physician's order.

Rationale

Administering parenteral fluids is an effective way to restore fluid balance when oral ingestion of fluid is contraindicated.

Provide ice chips and lip cream to relieve symptoms of mouth dryness.

Oral fluids in small, frequent amounts stabilize the digestive system. Hypotonic glucose-electrolyte solutions increase the net fluid absorption (Ackley & Ladwig, 2011).

BOX 39-8 NURSING CARE PLAN—cont'd

Interventions (Nursing Interventions Classification)*

Increase fluid intake when gastrointestinal symptoms have resolved, beginning with clear fluids and advancing to full fluids and light meals.

Prepare the patient for the diagnostic tests and possible antibiotic therapy.

Pain Management

Administer antiemetics and analgesics for the first 24 hours and re-evaluate.

Place a warm blanket on the patient's abdomen.

Rationale

When symptoms have resolved, beginning with clear fluids prevents recurrence of distress and minimizes gastrointestinal pain.

Pharmacotherapy is important for treating nausea, emesis, and pain.

Other comfort measures, such as using warm blankets, are important complementary pain management strategies.

Evaluation

Nursing Actions

Monitor ABG levels, vital signs, intake and output, daily weight, and bowel sounds.

Assess mucous membranes.

Patient Response and Finding

ABG analysis: pH = 7.36, PaO₂ = 95, bicarbonate = 35, PaCO₂ = 38.

Mucous membranes are moist.

Achievement of Outcome

Mrs. Topping's acid-base balance returns to normal. Her intake and output measurements are balanced. Her daily weight remains stable.

She is able to take clear fluids, and her intravenous rate is reduced.

*Outcome classification and intervention classification labels from Ackley, B. J., & Ladwig, G. B. (2011). *Nursing diagnosis handbook: An evidence-based guide to planning* (9th ed.). St Louis, MO: Mosby Elsevier.

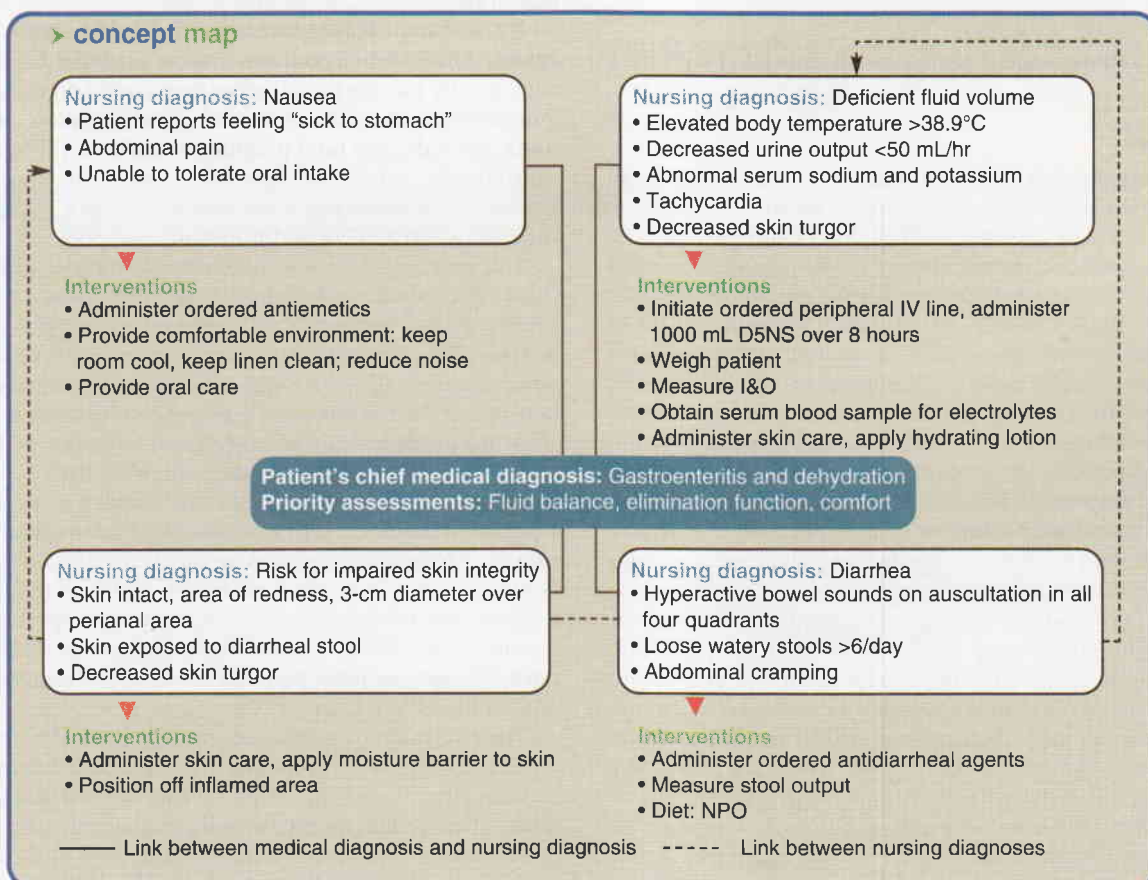

Figure 39-10 Concept map for a patient with gastroenteritis and dehydration. D5NS, Dextrose 5% in 0.9% sodium chloride; I&O, intake and output; NPO, nothing by mouth.

* BOX 39-9 PATIENT TEACHING

Primary Health Care and Patient Teaching: Preventing and Managing Chronic Kidney Disease

Chronic kidney disease is a major burden for both individuals and the health care system to carry. The accumulation of waste products and the fluid, electrolyte, and acid-base imbalances associated with this disease have many negative results. Primary health care for patients with chronic kidney disease can alleviate some of the morbidity, early mortality, and psychosocial and financial challenges for patients and their families. Cardiovascular disease is a major cause of death of people with chronic kidney disease. Patients should be taught that the progression of kidney disease can be slowed and cardiovascular risk reduced through the following measures:

- Smoking cessation
- Control of blood pressure
- Control of blood sugar for patients with diabetes
- Control of lipids, antiplatelet therapy
- Renin-angiotensin system antagonism
- Management of anemia
- Control of calcium and phosphate levels

Data from Barrett, B. J. (2003). Applying multiple interventions in chronic kidney disease. *Seminars in Dialysis*, 16, 157–164; and Curtis, B. M., Levin A., & Parfrey, P. S. (2005). Multiple risk factor intervention in chronic kidney disease: Management of cardiac disease in chronic kidney disease patients. *Medical Clinics of North America*, 89, 511–523.

orthopnea, and dependent edema are all associated with fluid retention.

Acute Care

Fluid, electrolyte, and acid-base imbalances can occur in all settings, although many patients are cared for in acute care settings. Today, management of the patient's complex medical care is completed in a shorter span of time at the same as there are expectations to perform more difficult technological skills.

Enteral Replacement of Fluids. Oral replacement of fluids and electrolytes is appropriate as long as the patient is not so physiologically compromised that oral fluids cannot be replaced rapidly. Patients unable to tolerate solid foods may still be able to ingest fluids. Oral rehydration solutions (ORS) have had a very positive impact on mortality related to diarrhea around the world. ORS are either glucose-electrolyte solutions or polymer-based solutions (e.g., made from rice, wheat, or maize). Recent evidence suggests that polymer-based solutions may be more effective in rehydration (Gregorio et al., 2009). You may also use strategies to encourage fluid intake such as frequently offering small sips of fluid, ice pops, and ice chips. Ice chips should be included in the intake and output measurements, at one-half the volume of the chips (i.e., 250 mL of ice chips = 125 mL). Hartling et al. (2006) conducted a systematic review and concluded that oral hydration is effective and safe in treating dehydration in children with gastroenteritis, particularly with low-osmolality solutions, in keeping with World Health Organization (WHO) recommendations. A key nursing role is to encourage children and their caregivers regarding oral rehydration.

Oral replacement of fluids is contraindicated if the patient has a mechanical obstruction of the gastrointestinal tract, is at

risk for aspiration, or has impaired swallowing. A feeding tube may be necessary such as when the patient's gastrointestinal tract is healthy, but the patient cannot ingest fluids (e.g., with impaired swallowing). Fluids can also be replaced through a gastrostomy or jejunostomy feeding tube or administered via a small-bore nasogastric feeding tube.

Restriction of Fluids. Patients who retain fluids and have **fluid volume excess (FVE)** require restricted fluid intake. Fluid restriction is often difficult for patients, particularly if they take medications that dry the oral mucous membranes, or if they breathe through the mouth. You should provide the rationale for fluid restrictions and the amount permitted. The patient and family need to understand that ice chips, gelatin, and ice cream are considered fluid. The patient should be involved in decisions regarding the amount of fluid and the distribution of fluids over the day. Patients on fluid restriction can swallow a number of pills with as little as 30 mL of liquid. Patients on fluid restriction require mouth care frequently to moisten mucous membranes, decrease the chance of mucosal drying and cracking, and maintain comfort.

Interventions for Acid-Base Imbalances. Nursing interventions to promote acid-base balance support prescribed medical therapies and are aimed at reversing the acid-base imbalance. Such imbalances can be life-threatening and require rapid correction. In collaboration with the physician, you must maintain a functional intravenous line and provide prescribed medications, such as insulin or sodium bicarbonate, and fluid and electrolyte replacement promptly. Patients with acid-base disturbances usually require repeated ABG analysis and close monitoring.

Parenteral Replacement of Fluids and Electrolytes. Fluid and electrolytes may be replaced through infusion directly into the blood rather than via the digestive system. Parenteral replacement includes administration of **crystalloids, colloids, and total parenteral nutrition (TPN)**. TPN is a nutritionally adequate hypertonic solution consisting of glucose, other nutrients, and electrolytes. See Chapter 42 for a full discussion of TPN and nutritional support.

The goal of intravenous fluid administration is to maintain fluid, electrolyte, and energy demands when patients are limited in their intake and to correct or prevent fluid and electrolyte disturbances from excess losses. Intravenous fluid administration allows for direct access to the vascular system, permitting the continuous infusion of fluids over a period of time. Intravenous fluid therapy must be continuously regulated to assess for changes in the patient's fluid and electrolyte balances. Knowledge of the correct ordered solution, the equipment needed, the procedures required to initiate an infusion, how to regulate the infusion rate and maintain the system, how to identify and correct problems, and how to discontinue the infusion is necessary for safe and appropriate therapy. Because of the risk of transmission of infectious diseases, standard precautions must be followed when administering parenteral fluids (see Chapter 32).

The two main categories of intravenous fluids are crystalloids and colloids. Crystalloids are used most commonly and include glucose, sodium chloride, and lactated Ringer's solutions. These solutions contain solutes that mix, dissolve, and cross semipermeable membranes. They vary in their tonicity. Colloids contain protein or starch (Phillips, 2005), which does not cross semipermeable membranes and therefore remains suspended and distributed in the extracellular space, primarily the intravascular space, for up to several days. Colloids

have been used to increase the osmotic pressure in the intravascular space to increase vascular volume in critical situations. Colloids are either semi-synthetic, such as dextran, pentastarch, or hetastarch, or human plasma derivatives, such as albumin, plasma proteins, or blood. Recent evidence suggests that crystalloids are as effective as colloids and are less costly (Gonzales, 2008; Perel, 2011).

Vascular Access Devices. Vascular access devices (VADs) are catheters, cannulas, or infusion ports designed for repeated access to the vascular system. These devices include peripheral vascular access devices (PVADs) and central vascular access devices (CVADs) and allow for parenteral fluid and electrolyte replacement, parenteral nutrition, and administration of medications. Peripheral cannulas are selected for short-term use, while central venous catheters (CVCs), midline catheters, peripherally inserted central catheters (PICCs), tunneled catheters (e.g., Hickman), and implanted ports (Figure 39-11) are for long-term use or for administration of medications or solutions that are irritating to veins. Other reasons for use of CVADs are limited or poor peripheral veins, the need for good access to administer large volumes of fluid, and the need for reliable measurement of fluids (Kelly, 2009). CVADs have become an essential tool in contemporary nursing practice in acute care and community settings (Casey & Elliot, 2010, p. 78). The Registered Nurses' Association of Ontario (RNAO) (2005, 2008a) suggests that you play an important role in the education of patients and family in relation to VADs and decisions regarding device selection. You also play a role in continually evaluating the need and appropriateness of a VAD (Lavery & Smith, 2007). The recommendations and discussion that follows are general guidelines; however, you should be aware of, and follow, specific institutional and manufacturers policy.

Peripheral Vascular Access Devices: Nursing Considerations. Comprehensive assessment is the first step in initiating any intravenous therapy (Hamilton, 2006; Lavery & Smith, 2007) (see Skill 39-1, Steps 2 to 6). Many factors are involved in device selection, including safety concerns, treatment goals and duration, access to services such as home intravenous programs, and physical limitations. Effective communication,

video

Delegation Considerations

In many provinces, monitoring intravenous therapy is included within the scope of practice for licensed and registered practical nurses. However, the delegating nurse is ultimately responsible for assessment and monitoring of the intravenous device. *The skill of initiating intravenous therapy should not be delegated to unregulated care providers (UCPs).* Other aspects of the patient's care may be delegated to UCPs. Instruct the UCP about the following:

- To inform the nurse if the patient complains of burning sensation, bleeding, swelling, or coolness at the catheter insertion site
- The prescribed flow rate and to report if the rate has slowed or increased
- To inform the nurse if the intravenous dressing becomes wet or if an electronic infusion device (EID) sounds
- To inform the nurse if the volume of fluid in the intravenous bag is low

Equipment

- Correct intravenous solution
- Proper catheter for venipuncture (the gauge will vary with the patient's body size and the reason for intravenous fluid administration). Select the smallest gauge and shortest length possible.
- Intravenous start kit (if available): may contain a sterile drape to place under the patient's arm, a tourniquet, cleansing and antiseptic preparations, dressings, and a small roll of sterile tape
- Local anaesthetic (optional)

For Intravenous Fluid Infusion

- Administration set (the choice depends on the type of solution and the rate of administration; infants and children, patients with cardiac or renal disease, and certain medications require microdrip tubing, which provides 60 gtt/mL)
- 0.22- μ m filter (if required by agency policy or if particulate matter is likely; the size appropriate to the type of solution)
- Extension tubing (used when a longer intravenous line is necessary or to avoid manipulation of the catheter insertion site with frequent tubing changes)
- Antiseptic swabs or sticks (chlorhexidine, povidone-iodine, alcohol)
- Disposable gloves

Continued

► SKILL 39-1 Initiating a Peripheral Intravenous Infusion—cont'd

- Tourniquet (Determine the type of tourniquet on the basis of the patient assessment, e.g., a blood pressure [BP] cuff [older adult] or a rubber band [infants]. Tourniquets can be a source of contamination; use a single-use product.)
- Nonallergenic tape and sterile tape (for use under the dressing)
- Waterproof pad (to place under patient's hand or arm)
- Intravenous pole
- Special patient gown with snaps at shoulder seams if available (makes removal with intravenous tubing easier)
- Needle disposal container (also called sharps container)
- Intravenous site protection device (optional)

For Normal Saline Lock

- Injection cap (also called intravenous plug, adapter)
- Intravenous loop or short piece of extension tubing
- 1 to 3 mL of sterile normal saline
- Needleless access device, or syringes and 25-gauge needles

Gauze Dressing Only

- 2 × 2 (5 cm × 5 cm) or 4 × 4 (10 cm × 10 cm) sterile gauze sponge
- Sterile tape

Transparent Dressing Only

- Transparent dressing

Procedure

STEPS

1. Review physician's order for type and amount of intravenous fluid, rate of fluid administration, and purpose of infusion. Follow seven rights for administration of medications (see Chapter 33).

RATIONALE

- An order requesting the initiation of a peripheral intravenous access and administration of an intravenous solution must be made by a physician before implementation of this procedure. Nurses assist in decision making for selection of appropriate access device.

Critical Decision Point: Health care providers do not write orders to "initiate peripheral access" or "perform venipuncture." "Start IV" may be written, followed by the exact intravenous therapy order. The order to perform venipuncture is implied. If the order is confusing or in question, clarify it with the health care provider before proceeding.

2. Observe for signs and symptoms indicating fluid or electrolyte imbalances that may be affected by intravenous fluid administration:

A. Peripheral edema

B. Greater than 20% change in body weight

C. Dry skin and mucous membranes

D. Distended neck veins

E. BP changes

F. Irregular pulse rhythm; tachycardia

G. Auscultation of abnormal lung sounds

H. Decreased skin turgor. Skin fails to return to normal position in three seconds after pinching.

- Provides baseline data for later evaluation of change in fluid and electrolyte status.
- Indicates expanded interstitial fluid volume, evident in dependent body parts (e.g., feet and ankles). Excess intravenous fluids will worsen this condition.
- Daily weights assist in documenting fluid retention or loss. Change in body weight of 1 kg corresponds to 1 L of fluid retention or loss.
- Frequently associated with FVD.
- Frequently associated with FVE or cardiovascular alterations.
- Elevations in BP may indicate volume excess, and decreased pressure may indicate FVD. These changes can be more sudden and pronounced in those patients with underlying cardiopulmonary disease.
- Rate and rhythm change can occur with changes in intravascular volume, as well as changes in potassium, calcium, or magnesium. Tachycardia may indicate cardiac compensation for reduced circulating volume, whereas irregular pulse may indicate arrhythmias secondary to electrolyte imbalance.
- With FVE, the cardiovascular system is unable to compensate for this excess and fluid builds up in the lungs, creating abnormal lung sounds, such as crackles.
- With decreased fluid volume, the skin when pinched remains in that state for several seconds. This is called "tenting."

Critical Decision Point: Changes in skin turgor are a less reliable indicator for older adult patients because of the natural loss in skin elasticity caused by the normal aging process.

I. Thirst

J. Anorexia, nausea, and vomiting

K. Decreased urine output

L. Behavioural changes

- Symptomatic of FVD. Very young, confused, and severely debilitated patients may not be able to indicate their thirst.
- May be present with FVE or FVD. These symptoms may also be present with the patient's underlying disease.
- During dehydration, the kidneys attempt to restore fluid balance by reducing urine production.
- May occur with FVD and acid-base imbalance. In addition, behavioural changes may be due to fever, the underlying condition, or preexisting disease.

► SKILL 39-1 Initiating a Peripheral Intravenous Infusion—cont'd

video

3. Assess patient's previous or perceived experience with intravenous therapy and arm placement preference (Lavery & Smith, 2007).
 4. Determine whether patient is to undergo any planned surgeries or is to receive blood infusion later.
 5. Assess laboratory data and patient's history of allergies.
 6. Assess for the following risk factors: child or older adult, presence of heart failure or renal failure, or low platelet count.
 7. Prepare patient and family by explaining the procedure, its purpose, and what is expected of the patient.
 8. Perform hand hygiene.
 9. Assist patient to comfortable sitting or supine position.
 10. Organize equipment on clean, clutter-free bedside stand or overbed table.
 11. Change patient's gown to the more easily removed gown with snaps at the shoulder, if available.
 12. Check intravenous solution, using the rights of drug administration (see Chapter 33). Make sure prescribed additives, such as potassium and vitamins, have been added. Check solution for colour, clarity, and expiration date. Check bag for leaks, which is best if done before reaching the bedside.
 13. Open sterile packages using sterile aseptic technique.
 14. Open the infusion set, maintaining sterility of both ends of tubing. Many sets allow for priming of tubing without removal of end cap.
 15. Place roller clamp about 2 to 5 cm below drip chamber and move roller clamp to closed position (see Step 15 illustrations).
- Determines level of emotional support and instruction necessary. If hypersensitive to venipunctures, a local anaesthetic may be indicated. The local anaesthetic needs to be applied 5–10 minutes prior to insertion (Lehne, 2010).
 - Allows nurse to select catheter gauge, and avoids placement in an area that will interfere with medical procedures.
 - May reveal information that affects insertion of devices, such as FVD, anemia, or allergy to iodine, adhesive, or latex.
 - Fluid imbalances develop more rapidly in extremely young patients (infants) and older patients because such patients have proportionately larger ECF volume, patients with heart failure may require fluid restriction and cannot adapt to sudden increases in vascular volume, and patients with renal failure cannot eliminate excess ECF. A low platelet count predisposes patients to bleeding at intravenous site.
 - Decreases anxiety and promotes cooperation.
 - Reduces transmission of microorganisms.
 - Enables patient to extend arm.
 - Reduces risk of contamination and accidents.
 - Use of a special intravenous gown facilitates safe removal of the gown.
 - Intravenous solutions are medications and should be carefully checked to reduce the risk of error. Solutions that are discoloured, contain particles, or are expired are not to be used. (Some solutions may have slight discolouration [e.g., be pink-tinged] and still be suitable for use.) Leaky bags present an opportunity for infection and must not be used.
 - Maintains sterility of equipment and reduces spread of microorganisms.
 - Prevents bacteria from entering infusion equipment and bloodstream.
 - Close proximity of roller clamp to drip chamber allows more accurate regulation of flow rate. Moving clamp to closed position prevents accidental spillage of fluid.

Step 15 A, Roller clamp in open position. B, Roller clamp in closed position.

Continued

► SKILL 39-1 Initiating a Peripheral Intravenous Infusion—cont'd

video

16. Remove protective sheath over intravenous bag port (see Step 16 illustration). For bottled intravenous solution, remove metal cap and metal and rubber discs beneath cap. Use caution to avoid touching exposed opening.
 17. Insert infusion set into fluid bag or bottle by removing protector cap from tubing insertion spike (keeping spike sterile) and inserting spike into opening of intravenous bag (see Step 17 illustration). Cleanse rubber stopper on glass-bottled solution with antiseptic and insert spike into black rubber stopper of intravenous bottle. Hang solution container on intravenous pole at a minimum height of 90 cm above planned insertion site.
- Provides access for insertion of infusion tubing into solution.
 - Prevents contamination of solution from contaminated insertion spike.
 - Container heights of approximately 1 m are usually sufficient to overcome venous pressure and other resistance from tubing and catheter.

Step 16 Removing protective sheath from intravenous bag port.

Source: Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., p. 747, Skill 28-1, Step 7d). St Louis, MO: Mosby.

Step 17 Inserting spike into intravenous bag. **Source:** Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., p. 747, Skill 28-1, Step 7e). St Louis, MO: Mosby.

18. Compress drip chamber and release, allowing it to fill one-third to one-half full (see Step 18 illustration). Open clamp and prime infusion tubing by filling with intravenous solution, carefully inverting valves and ports in sequence as the solution moves through the tubing.
 19. Remove tubing protector cap (some tubing can be primed without removal) and slowly release roller clamp to allow fluid to travel from drip chamber through tubing to needle adapter. Return roller clamp to closed position after tubing is primed (filled with intravenous fluid).
- Creates vacuum effects; fluid enters drip chamber to prevent air from entering tubing. By inverting valves and ports, you allow them to fill with fluid, minimizing air bubbles.
 - Slow filling of tubing decreases turbulence and chance of bubble formation. Removes air from tubing and permits tubing to fill with solution. Closing the clamp prevents accidental loss of fluid.

► SKILL 39-1 Initiating a Peripheral Intravenous Infusion—cont'd

20. Be certain tubing is clear of air and air bubbles. To remove small air bubbles, firmly tap intravenous tubing where air bubbles are located. Check entire length of tubing to ensure that all air bubbles are removed (see Step 20 illustration).

- Large air bubbles can act as emboli. Air bubbles may contribute to anxiety related to intravenous therapy and may cause EID to alarm increasing anxiety further.

Step 18 Squeezing drip chamber to fill with fluid. **Source:** Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., p. 747, Skill 28-1, Step 7f). St Louis, MO: Mosby.

Step 20 Removing air bubbles from tubing. **Source:** Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., p. 747, Skill 28-1, Step 7h). St Louis, MO: Mosby.

Critical Decision Point: Do not touch spike. It is sterile. If contamination occurs (e.g., spike is accidentally dropped on the floor), then discard intravenous tubing and obtain a new one.

Critical Decision Point: Extra extension tubing may be added to intravenous tubing to allow for more length, which will enable the patient to move more freely while still keeping the intravenous line stable. But remember, adding extensions increases risk for infection.

21. Replace tubing cap protector on end of tubing.
22. *Optional:* Prepare normal saline lock for infusion. If a loop or short extension tubing is needed, use sterile technique to connect the intravenous plug to the loop or short extension tubing. Inject 1 to 3 mL normal saline through the plug and through the loop or short extension tubing.
23. Apply disposable gloves. Eye protection and mask may be worn (see agency policy) if splash or spray of blood is possible. *Note:* Gloves can be left off to locate vein but must be applied before preparing site.

- Maintains system sterility.
- Priming the extension tubing and plug prevents introduction of air into the vein.
- Reduces transmission of microorganisms. Decreases exposure to HIV, hepatitis, and other bloodborne organisms (Infusion Nurses Society [INS], 2006).

Critical Decision Point: Do not shave area with a razor. Shaving may cause microabrasions and predispose patient to infection. Clipping excess hair is appropriate (RNAO, 2008b).

24. Identify accessible vein for intravenous placement. Apply tourniquet 10 to 15 cm above the proposed insertion site (see Step 24 illustration). Position tourniquet so that ends are away from proposed venipuncture site. Check for presence of radial pulse. *Option:* Apply BP cuff instead of tourniquet. Inflate to a level just below patient's normal diastolic pressure. Maintain inflation at that pressure until venipuncture is completed.

- Tourniquet should be tight enough to impede venous return but not occlude arterial flow.

Continued

► SKILL 39-1 Initiating a Peripheral Intravenous Infusion—cont'd

video

25. Select the vein. Common intravenous sites for the adult include cephalic, basilic, and median cubital veins (see Figure 39-13).
- Use the most distal site in the nondominant arm, if possible.
 - Avoid areas that are painful to palpation.
 - Select a vein large enough for catheter placement.
 - Choose a site that will not interfere with patient's activities of daily living or planned procedures.
 - Use the fingertips to palpate the vein by pressing downward and noting the resilient, soft, bouncy feeling as the pressure is released (see Step 25E illustration).

- Venipuncture should be performed distal to proximal, which increases the availability of other sites for future intravenous therapy.
- May indicate inflamed vein.
- Prevents interruption of venous flow while allowing adequate blood flow around the catheter.
- Selection of an appropriate site will minimize risk of injury and loss of the IV.
- Fingertips are more sensitive and are better to assess vein condition.

Step 24 Apply tourniquet. **Source:** Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., p. 748, Skill 28-1, Step 10). St Louis, MO: Mosby.

Step 25E Palpate vein for resilience.

- Promote venous distension by instructing the patient to open and close the fist several times, lowering the patient's arm in a dependent position, applying warmth to the arm for several minutes, and rubbing or stroking the patient's arm from distal to proximal below proposed site.

- These activities increase blood flow to the area of insertion. When these techniques are properly used, they foster venous dilation and access to the vein.

Critical Decision Point: Avoid vigorous rubbing and multiple tapping of patient's veins. These techniques may cause injury to the vein, such as a hematoma, or cause venous constriction.

- Avoid sites distal to previous venipuncture site, sclerosed or hardened cordlike veins, infiltrated site or phlebotic vessels, bruised areas, and areas of venous valves or bifurcation. Avoid veins in antecubital fossa and ventral surface of the wrist.
 - Avoid fragile dorsal veins in older adults and vessels in an extremity with compromised circulation (e.g., in cases of mastectomy, dialysis graft, or paralysis).
26. Release tourniquet temporarily and carefully. Clip arm hair with scissors (if necessary). Do not shave area.
- Such sites increase the risk of infiltration of newly placed intravenous line and excessive vessel damage.
 - Veins in the antecubital fossa are used for blood draws, and placement in this area limits mobility. Inner wrist contains numerous tendons that could be damaged.
 - Venous alterations can increase risk of complications (e.g., infiltration and decreased catheter dwelling time).
 - Hair impedes venipuncture and adherence of dressing. Shaving can cause microabrasions and predispose patient to infection.

► SKILL 39-1 Initiating a Peripheral Intravenous Infusion—cont'd

27. (If area of insertion appears to need cleansing, use soap and water first.) Cleanse insertion site using firm, circular motion (centre to outward) in concentric circles 5–7.5 cm from insertion site. Use antiseptic preparation as a single agent or in combination, according to agency policy. Two percent chlorhexidine gluconate is the antiseptic cleansing agent of choice. Povidone-iodine is a topical anti-infective agent that reduces skin surface bacteria; 70% alcohol is another antiseptic cleansing agent. Povidone-iodine must dry to be effective in reducing microbial counts. Avoid touching the cleansed site. Allow the site to dry for at least two minutes (see Step 27 illustration). If skin is touched after cleansing, repeat cleansing procedure (Lavery & Ingram, 2006).

Step 27 Cleanse site chosen for insertion. **Source:** Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., p. 750, Skill 28-1, Step 16). St Louis, MO: Mosby.

28. Reapply tourniquet or BP cuff.

Critical Decision Point: Do not use povidone-iodine if the patient is allergic to iodine; use an alternative cleansing agent.

29. Perform venipuncture. Anchor vein by placing thumb over vein beneath insertion site and by stretching the skin against the direction of insertion 5 to 7.5 cm distal to the site (see Step 29 illustration). Warn patient of a sharp stick. Puncture skin and vein, holding catheter at 10- to 30-degree angle with the bevel pointed upward.

- A. Butterfly needle:** Hold needle at 10- to 30-degree angle with bevel up slightly distal to actual site of venipuncture.
B. Needleless safety device: Insert device (see Step 29B illustration) with bevel up at 10- to 30-degree angle slightly distal to actual site of venipuncture in the direction of the vein.

Step 29 Stabilize vein below insertion site with skin taut. **Source:** Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., p. 750, Skill 28-1, Step 18). St Louis, MO: Mosby.

- Air-drying prevents chemical reactions between agents and allows time for maximum microbicidal activity of agents (INS, 2006).
- Touching the cleansed area would introduce organisms from nurse's hand to the site.

- The vascular access device selected should be the smallest gauge and shortest length that will accommodate the therapy (INS, 2006).
- Places needle parallel to vein. When vein is punctured, risk of puncturing posterior vein wall is reduced.
- Superficial veins require a smaller angle; deeper veins require a greater angle.

Step 29B Puncture skin with catheter and enter the vein. **Source:** Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., p. 750, Skill 28-1, Step 18a). St Louis, MO: Mosby.

► SKILL 39-1 Initiating a Peripheral Intravenous Infusion—cont'd

video

Critical Decision Point: No more than two attempts at inserting an intravenous line should be made by a single nurse (INS, 2006).

30. Look for blood return through tubing of butterfly needle or flashback chamber of ONC, indicating that needle has entered vein (see Step 30 illustration, part A). Lower catheter or needle until almost flush with skin. Advance butterfly needle or loosen stylet and advance ONC until hub is near the insertion site (see Step 30 illustration, part B). Do not reinsert the stylet once it is loosened.

- Increased venous pressure from tourniquet increases backflow of blood into catheter or tubing.
- Lowering the angle and advancing the cannula slightly allow for full penetration of vein wall, placement of catheter within vein's inner lumen, and easy advancement of catheter off stylet.
- Threading catheter up to hub reduces the risk of introduction of infectious organisms along the catheter length. Reinsertion of the stylet can cause catheter damage and potential catheter embolization.
- Techniques for retracting stylet vary with each IV device.

Step 30 A, Blood return in flashback chamber, catheter lowered flush with skin. B, Advance catheter into vein; use safety device push-tab. **Source:** Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., p. 751, Skill 28-1, Step 19b). St Louis, MO: Mosby.

31. Stabilize the catheter. Apply gentle but firm pressure with the index finger of nondominant hand 3 cm above insertion site. Release tourniquet or BP cuff with dominant hand and retract stylet from ONC. Do not recap the stylet. For a safety device, slide the catheter off the stylet while gliding the protective guard over the stylet. A click indicates the device is locked over the stylet.
32. Quickly connect adapter of primed fluid administration set or saline lock to hub of ONC or butterfly tubing. Be sure connection is secure. Do not touch point of entry of adapter.
- 33A. Release roller clamp slowly to begin infusion at a rate to maintain patency of intravenous line.
- 33B. **Intermittent infusion:** Continue to stabilize catheter with nondominant hand and attach injection cap of adapter. Insert prefilled flush solution into injection cap. Flush slowly (see Step 33B illustration). Maintain thumb pressure on syringe during withdrawal or close clamp on extension tubing of injection cap while still flushing last 0.2–0.4 mL of flush solution.

- Permits venous flow, reduces backflow of blood, and prevents accidental withdrawal or dislodgement.
- Prompt connection of infusion set maintains patency of vein.
- Maintains sterility.
- Permits venous flow and prevents clotting of vein and obstruction of flow of intravenous solution.
- Positive pressure in the catheter prevents reflux of blood into the catheter lumen (Phillips, 2005).

Step 33B Flush injection cap slowly. **Source:** Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., p. 752, Skill 28-1, Step 22). St Louis, MO: Mosby.

SKILL 39-1 Initiating a Peripheral Intravenous Infusion—cont'd

Critical Decision Point: Be sure to calculate rate so as not to infuse intravenous solution too rapidly or too slowly.

34. Tape or secure catheter (see Step 34 illustration).

A. If applying transparent dressing, secure catheter with nondominant hand while preparing to apply dressing. Tape over catheter hub (see Step 34A illustration).

Step 34 Catheter stabilization device. **Source:** Courtesy of C. R. Bard, Inc. From Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., p. 752, Skill 28-1, Step 23a). St Louis, MO: Mosby.

B. If applying a gauze dressing:

- (1) Tape the intravenous catheter as with Step 34A. Avoid applying tape around the extremity.

36. Observe site for swelling.

37. Apply sterile dressing over site.

A. Transparent dressing

- (1) Carefully remove adherent backing. Apply one edge of dressing and then gently smooth remaining dressing over site, leaving connection between IV tubing and the end of catheter hub uncovered (see Step 37A[1] illustration).
- (2) Tape with a 2.5 cm width tape over IV tubing or extension set. Do not apply tape over transparent dressing (see Step 37A2 illustration).

Step 37A(1) Apply transparent dressing. **Source:** Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., p. 753, Skill 28-1, Step 25a[1]). St Louis, MO: Mosby.

- Securing the catheter and tubing prevents movement and tension on the device, reducing mechanical irritation and possible phlebitis or infection. Procedures for taping and securing catheter vary with devices and with agency policy. Catheter stabilization device, transparent dressing or tape, and gauze are three common options. Manufacturer provided catheter stabilization devices reduce the risk of complications from PVAD (Rosenthal, 2007).

Step 34A Tape over catheter hub. **Source:** Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., p. 752, Skill 28-1, Step 23c). St Louis, MO: Mosby.

- Tape placed underneath the dressing should be sterile; nonsterile tape is a potential source of pathogenic bacteria.
- Taping around extremity could result in a “tourniquet effect” and impede venous return.
- Any swelling suggests the catheter has been dislodged or was unsuccessfully inserted and must be removed.

- Transparent dressings are occlusive to moisture and microorganisms. Transparent dressings allow continuous inspection of the intravenous site, are more comfortable, and permit patients to bathe and shower without saturating the dressing.

Step 37A(2) Place tape over transparent dressing. **Source:** Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., p. 753, Skill 28-1, Step 25a[2]). St Louis, MO: Mosby.

► SKILL 39-1 Initiating a Peripheral Intravenous Infusion—cont'd

video

B. Sterile gauze dressing

- (1) Fold a $2 \times 3 \times 2$ gauze in half and cover with a 2.5 cm wide piece of sterile tape extending about 2.5 cm from each side. Place it under the tubing–catheter hub junction (see Step 37B[1] illustration).
- (2) Curl a loop of tubing alongside the arm and place a second piece of tape directly over the padded 2×2 gauze, securing tubing in two places (see Step 37B[2] illustrations).

Step 37B(1) Place 2×2 gauze over insertion site and catheter hub.

Source: Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., p. 753, Skill 28-1, Step 25b[1]). St Louis, MO: Mosby.

- Tape on top of tape makes it easier to access hub–tubing junction. Securing loop of tubing reduces risk of dislodging catheter from accidental pull.
- Gauze is less expensive than transparent dressing and may also be useful for bleeding or excessive moisture at the site.

Step 37B(2) Apply 2×2 gauze dressing under tubing junction.

Source: Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., p. 753, Skill 28-1, Step 25b[2]). St Louis, MO: Mosby.

38. Secure tubing. Curl a loop of tubing along the arm and place a second piece of 2.5 cm tape over the tubing to secure (see Step 38 illustration).

39. Prepare the equipment according to expected frequency of use.

A. For intravenous fluid administration: Adjust flow rate to correct drops per minute or connect to EID (see Skill 39-2, Steps 9 to 15).

B. For intermittent use: Saline lock. Flush with 3 mL of sterile normal saline at prescribed frequency or agency policy.

40. Label dressing with date, time, gauge size and length of catheter, and your initials (see Step 40 illustration).

Step 38 Loop and secure tubing. **Source:** Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., p. 754, Skill 28-1, Step 26). St Louis, MO: Mosby.

- Maintains correct rate of flow for intravenous solution. Flow can fluctuate; therefore, it must be checked at intervals.
- Maintains patency of intravenous catheter. While some authors recommend heparin lock, the RNAO (2008b recommends use of saline for flushing and locking peripheral short catheters, after each use and daily if not in use.
- Allows for easy recognition of type of device and time interval for site rotation.

Step 40 Label IV dressing. **Source:** Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., p. 754, Skill 28-1, Step 28). St Louis, MO: Mosby.

41. Dispose of used needles in appropriate sharps container. Discard supplies. Remove gloves and perform hand hygiene.

- Reduces transmission of microorganisms and protects staff from injury.

► SKILL 39-1 Initiating a Peripheral Intravenous Infusion—cont'd

42. Observe patient every hour to determine whether fluid is infusing correctly:
 - A. Check whether correct amount of solution is infused as prescribed by looking at time tape.
 - B. Count flow rate or check rate on infusion pump.
 - C. Check patency of intravenous catheter or needle.
 - D. Observe patient for signs of discomfort.
 - E. Inspect insertion site for absence of phlebitis (see Table 39-7), infiltration (see Table 39-8), or inflammation.
 43. Document IV insertion including date, time, device selected (size, type, length, brand), site, number of attempts, name, and professional designation. A special parenteral therapy flow sheet may be used. Record patient's response to intravenous fluid, amount infused, and integrity and patency of system every four hours or according to agency policy.
 44. Observe patient every hour to determine response to therapy (i.e., measure vital signs, conduct postprocedure assessments).
- Correct administration of fluid volume prevents fluid imbalance.
 - Accurate monitoring of rate further ensures correct volume administration.
 - Precise description of insertion site is important for future consideration of sites.
 - Evaluation of parenteral therapy is an important part of the nursing process.
 - Provides continuous evaluation of type and amount of fluid delivered to patient. Hourly inspection prevents accidental fluid overload or inadequate infusion rate and identifies early incidence of vein inflammation or tissue damage. Intravenous fluids and additives are given to maintain or restore fluid and electrolyte balance. They can also cause unexpected effects, which can be serious.

Unexpected Outcomes

FVD, as manifested by decreased urine output, dry mucous membranes, hypotension, and tachycardia

FVE, as manifested by crackles in lungs, shortness of breath, and edema

Electrolyte imbalances, as manifested by abnormal serum electrolyte levels; changes in mental status, neuromuscular function, and vital signs; and other signs and symptoms

Infiltration, as indicated by swelling and possible pitting edema, pallor, coolness, pain at insertion site, and possible decrease in flow rate

Phlebitis, as indicated by pain, increased skin temperature, and erythema along path of vein

Bleeding at venipuncture site

Related Interventions

- Notify physician; may require readjustment of infusion rate.
- Reduce intravenous flow rate if symptoms appear and notify physician.
- Notify physician. Additives in intravenous or type of intravenous fluid may be adjusted.
- Stop infusion and discontinue intravenous therapy. Elevate affected extremity. Restart new intravenous line if continued therapy is necessary.
- Stop infusion and discontinue intravenous therapy. Restart new intravenous line if continued therapy is necessary.
- Place moist, warm compress over area of phlebitis.
- Bleeding from vein is usually slow, continuous seepage. Common in patients who have received heparin or have a bleeding disorder or if the intravenous site is over bend in arm or hand.
- If bleeding occurs around venipuncture site and catheter is within vein, gauze dressing may be applied over site. Eventually, intravenous therapy may need to be discontinued.
- Blood on the dressing can result when the administration set becomes disconnected from the catheter's hub. When blood appears on the dressing, verify that the system is intact and change the dressing.

Reporting

- Report the following to oncoming nursing staff: type of fluid, flow rate, status of venipuncture site, amount of fluid remaining in present solution, expected time to hang next intravenous bag or bottle, and any side effects.

Home Care Considerations

- Teach patient and family about hand hygiene and aseptic technique for all care related to the intravenous site and equipment.
- Teach caregiver to apply pressure with sterile gauze if catheter falls out and, if patient is on anticoagulant therapy, to tape several pieces of sterile gauze in place for at least 20 minutes with pressure or until bleeding stops.
- Teach patient and caregiver to perform tub bath without getting intravenous tubing wet and to unplug pump first if one is used. For showering, the patient must protect the intravenous site and dressing from getting wet by covering them completely with plastic.
- Teach patient and family to monitor intake and output using measuring devices.
- Teach patient and family to dispose of open and sheathed needles into sharps container. All sharps containers must be stored in safe area away from children.

allowing time for questions, and education regarding the signs of complications are important to preventing and managing risks (Lavery & Smith, 2007).

Insertion and management of a PVAD is now considered a routine nursing responsibility and skill. The management of PVADs requires careful monitoring of the site, patency, and dressing. The site should be assessed for infiltration and phlebitis (Groll et al., 2010) (Table 39-7 and 39-8). Most treatments requiring intravenous access for more than one week are best suited to midline, PICC, or implanted ports (RNAO, 2008b). Scales to assess for phlebitis and infiltration are important tools for nurses initiating and managing PVADs (Box 39-10).

Central Vascular Access Devices: Nursing Considerations. A CVAD is a venous access device with a tip that terminates in a great vessel, preferably in the lower third of the

* BOX 39-10 RESEARCH HIGHLIGHT

Using Phlebitis and Infiltration Scales for Assessing PVAD

Research Focus

Phlebitis and infiltration are common complications related to IV therapy. Two scales, developed by the Infusion Nurses Society (INS), are used to assess the extent of these complications. A study was done by a team of Canadian researchers to evaluate the scales to evaluate the scales' reliability, validity, and ease of use.

Research Abstract

The study used observation in a hospital setting and with a home nursing agency, for a total of 182 participants and 416 observations. Each participant was observed up to four times by two observers. The participants' charts were also audited. The research nurses used a data collection tool and observation form for each participant. The study evaluated the phlebitis and infiltration scales for four properties: acceptability, feasibility, reliability, and validity. The researchers concluded that the scales are easy to use and did not take long to complete. The scales were reliable and valid in both settings. The researchers also found that nurses who used the tools identified more cases of phlebitis and infiltration than was recorded in the participants' charts. These findings support the use of the INS Phlebitis and Infiltration Scales in a variety of settings.

Evidence-Informed Practice

Nurses in all settings are positioned to assess for complications related to PVADs.

Scales to assess for phlebitis and infiltration are important tools for nurses initiating and managing PVADs.

Reference: Groll, D., Davies, B., Mac Donald, J., Nelson, S., & Virani, T. (2010). Evaluation of the psychometric properties of the phlebitis and infiltration scales for the assessment of complications of peripheral vascular access devices. *Journal of Infusion Nursing*, 33(6), 385–390.

superior vena cava; however, the upper right atrium is currently an acceptable site (Hadaway, 2008, p. 35). The catheters are available in a variety of lengths, sizes, and numbers of lumens and are often made of silicone or polyurethane. The most common insertion sites are the internal jugular and subclavian veins; the right internal jugular vein is considered the best option (Casey & Elliot, 2010, p. 80). Skin-tunnelled catheters (STC) are tunnelled from the entry site, subcutaneously, to the preferred vein, where the catheter is inserted and advanced into the superior vena cava (Green, 2008, p. 44). PICCs are inserted through a peripheral vein, such as the basilic, median cubital, or cephalic vein and terminate in the superior vena cava (Hamilton, 2006).

You need to be able to recognize the following complications: pneumothorax, arterial puncture, hemorrhage, cardiac tamponade, air embolus, hemothorax, nerve injury, hydrothorax, infection, catheter occlusion, and phlebitis. You also need to be aware of strategies to prevent these complications when caring for patients with a CVAD. Evidence-informed and vigilant nursing care is important on insertion and in the maintenance of all CVADs. Aseptic technique and diligent hand hygiene are essential for all aspects of care. Prior to insertion, chlorhexidine gluconate 2% in 70% isopropyl alcohol should be applied properly and allowed to dry. Maximal barrier precautions (including gown, mask, cap, and full drape) and ultrasound guided procedure are key recommendations for

insertion (Casey & Elliot, 2010, p. 82). Nurses must ensure that the tip placement or location has been verified and documented before the CVAD is used (Hadaway, 2008, p. 35). Finally, the date of insertion must be documented.

Maintenance recommendations are aimed at maintaining patency and preventing complications, specifically *catheter-related bloodstream infection* (CR-BSI). The manufacturer's stabilization device is preferred for PICCs and CVCs, although sterile tape or surgical strips can be used (Hadaway, 2008, p. 37). Sterile, transparent, semipermeable membrane dressings are recommended (Hadaway, 2008, p. 37). Sterile gauze and tape is accepted; however, it does not have the same advantages as transparent, semi-occlusive dressings, which allow for inspection and prevention of infection. Dressings are assessed daily or when they become wet, soiled, or loose. The new dressing will be labelled with the site, type of CVAD, length, date, time, and your initials. Gauze dressing may be changed as often as every 48 hours, and transparent dressing may be left intact for up to five to seven days. In the case of an STC, no dressing is required once the wound has healed unless the patient prefers one (Green, 2008, p. 45).

The external catheter should be measured and documented daily to ensure the catheter remains in the correct placement. The insertion site should be assessed daily for tenderness, signs of infection, erythema, warmth, and edema and should include palpation. The chest and neck should be accessed for engorged veins and for difficulty with movement. You would also assess for signs of systemic infection, such as fever, chills, and hypotension (Casey & Elliot, 2010, p. 78).

Prior to accessing a CVAD, Casey and Elliot (2010) recommend a 15-second rub with chlorhexidine. New antimicrobial devices and approaches to preventing CR-BSI are being developed and include antimicrobial catheters, needleless access devices, dressings, and lock solutions (Casey & Elliot, p. 84). To prevent occlusion of the CVAD, the device is flushed and assessed for patency according to institutional policy. The use of heparin for flushing and locking is currently an area for further study and future recommendations (e.g., Mitchell et al., 2009; RNAO, 2008a). Totally implantable ports, used for long-term treatment such as chemotherapy, are inserted surgically and are accessed by inserting a needle through the skin into the device. They can be used up to 2000 times (Kelly, 2009, p. s11) and have the lowest incidence of infection (Casey & Elliot, 2010, p. 80).

Patient and family education is required for all patients with a CVAD. Care requirements and restrictions should be included.

Administration of Intravenous Therapy

Types of Solutions. Many prepared intravenous solutions are available for use (Table 39-9). Solutions are classified as **hypertonic**, **isotonic**, or **hypotonic**. **Osmolarity**, reflecting the osmolar concentration in 1 L of solution (mOsm/L), is most often used to describe fluids outside the body (Hannon et al., 2010). A solution with the same osmolarity as blood plasma is called isotonic. A hypertonic solution, with a higher osmotic pressure, such as 3% sodium chloride, pulls fluid from cells, causing them to shrink. An isotonic solution, with the same osmotic pressure as plasma, such as 0.9% sodium chloride, expands the body's fluid volume without causing a fluid shift from one compartment to another. A hypotonic solution, with an osmotic pressure lower than plasma, such as 0.45% sodium chloride, moves fluid into the cells, causing them to enlarge. Each of these actions occurs through osmosis.

► TABLE 39-9 Intravenous Solutions

Solution	Concentration	Other Names
Dextrose in Water Solutions		
Dextrose 5% in water*	Isotonic	D5W
Dextrose 10% in water	Hypertonic	D10W
Saline Solutions		
0.45% sodium chloride (half normal saline)	Hypotonic	1.2 NS 0.45% NS
0.33% sodium chloride (one-third normal saline)	Hypotonic	1.3 NS
0.9% sodium chloride† (normal saline)	Isotonic	NS 0.9% NS 0.9% NaCl
3%–5% sodium chloride	Hypertonic	3%–5% NS 3%–5% NaCl
Dextrose in Saline Solutions		
Dextrose 5% in 0.9% sodium chloride	Hypertonic	D50.9% NaCl D50.9% NS D5NS
Dextrose 5% in 0.45% NaCl sodium chloride	Hypertonic	D50.45% NaCl D50.45% NS D51.2 NS
Multiple Electrolyte Solutions		
Lactated Ringer's solution‡	Isotonic	LR
Dextrose 5% in lactated Ringer's solution	Hypertonic	D5LR

*Dextrose is quickly metabolized, leaving free water to be distributed evenly in all fluid compartments (Heitz & Horne, 2005).

†Although it is isotonic because the total concentration of electrolytes equals plasma concentration, sodium chloride contains 154 mmol of both sodium and chloride, which is a higher concentration of these electrolytes than is found in the plasma, which can cause fluid volume excess (Heitz & Horne, 2005).

‡Contains sodium, potassium, calcium, chloride, and lactate.

In general, isotonic fluids are used most commonly for extracellular volume replacement (e.g., FVD after prolonged vomiting). The decision to use a hypotonic or a hypertonic solution is based on the specific fluid and electrolyte imbalances. For example, the patient with a hypertonic fluid imbalance will in general receive a hypotonic intravenous solution to dilute the ECF and rehydrate the cells. All intravenous fluids should be given carefully, especially hypertonic solutions, because these pull fluid into the vascular space by osmosis, resulting in an increased vascular volume that can lead to pulmonary edema, particularly in patients with heart or renal failure. Certain additives, most commonly vitamins and potassium chloride, are frequently added to intravenous solutions.

safety alert Under no circumstances should potassium chloride (KCl) be given by intravenous push. Direct intravenous infusion of KCl may cause death. If an intravenous fluid requires additives, a physician's order must specify the required additives: for example, "1000 mL D51/2 NS with 20 mmol/L KCl at 125 mL/hour."

Patients with normal renal function who are receiving nothing by mouth should have potassium added to intravenous solutions. The body cannot conserve potassium, and even when the serum level falls, the kidneys continue to excrete potassium. Without oral or parenteral potassium intake, hypokalemia can develop quickly. Conversely, you should verify that the patient has adequate renal function before administering an intravenous solution containing potassium because hyperkalemia can develop quickly.

Equipment. Correct selection and preparation of intravenous equipment are necessary for safe and quick placement of an intravenous line (Figure 39-12). Because fluids are instilled

into the bloodstream, sterile technique is necessary; have all equipment organized for efficient insertion (Skill 39-1). Intravenous cannulas are available in a variety of gauges. The larger the gauge, the smaller the diameter of the cannula is. These cannulas are plastic tubing threaded over a needle. Once the cannula is inserted into the vein, the needle is withdrawn, leaving the cannula in place. Intravenous tubing or an intermittent infusion device, such as a needleless port, is then connected. An electronic infusion pump as well as hourly visual monitoring of the cannulation site is recommended to prevent risks associated with peripheral venous access (Lavery & Smith, 2007, p. 1378).

safety alert Intravenous pumps or volume control devices ensure a prescribed rate of infusion. A prescribed rate of infusion is vital for children, patients with renal or cardiac failure, and critically ill patients. Electronic infusion devices must be used for medications that require precise rates of administration.

Figure 39-12 Options for intravenous access device.

Initiating an Intravenous Line. A venipuncture is a technique in which a vein is punctured through the skin by a sharp rigid stylet (e.g., butterfly needle or metal needle), a partially covered plastic catheter (over-the-needle catheter), or a needle attached to a syringe. When veins are fragile or collapse, venipuncture may become extremely difficult. For these difficult cases, venipuncture should be performed by an experienced, skilled practitioner. Skill 39-1 describes venipuncture for intravenous fluid infusion.

Venipuncture Site. After the equipment is collected at the bedside, prepare to place the intravenous line by assessing the patient for a venipuncture site (see Skill 39-1, Step 25A). Common intravenous puncture sites are the hand and the arm (Figure 39-13). The use of the foot for an intravenous site is common with children but is avoided in the adult because of the danger of thrombophlebitis (INS, 2006). Recent review of the literature does not currently support replacing a PVAD every 72 hours and instead supports this when clinically indicated; however, you will follow agency policy (Webster et al., 2010).

When assessing the patient for potential venipuncture sites for intravenous infusion, you should consider conditions and contraindications that exclude certain sites. Because children

Figure 39-13 Common intravenous sites.

* BOX 39-11 FOCUS ON OLDER ADULTS

Protection of Skin and Veins

- Use the smallest gauge cannula or needle possible (e.g., 22 to 24 gauge). Veins are very fragile, and a smaller gauge allows better blood flow to provide increased hemodilution of the intravenous fluids or medications.
- Avoid the back of the hand, which may compromise the patient's need for independence and mobility.
- Impaired skin integrity may lead to susceptibility for tearing, venous sclerosis, and difficulty detecting complications.
- Avoid placement of an intravenous line in veins that are easily bumped because less subcutaneous support tissue is present.
- If the patient has fragile skin and veins, use minimal or no tourniquet pressure.
- After applying a tourniquet, venous pressure rises rapidly, the vein is overstretched, and puncture with even a thin needle can rupture the wall of the vein.
- If using a tourniquet, place it over the patient's sleeve to decrease shearing of fragile skin.
- With loss of supportive tissue, veins tend to lie more superficially; lower the insertion angle for venipuncture to 5 to 15 degrees (Coulter, 2004; INS, 2006; Rosenthal, 2005).
- If the patient has lost subcutaneous tissue, the veins lose stability and will roll away from the needle. To stabilize the vein, apply traction to the skin below the projected insertion site.
- Secure the device with mesh dressing or a securement device for protection (Coulter, 2004).
- Nutritional deficiencies promote fluid to migrate into tissues surrounding vessels, making intravenous access more difficult.
- Multiple medication usage (e.g., anticoagulants, antibiotics, and steroids) increases the likelihood of fragile, transparent skin that bruises and bleeds easily.
- Dehydration related to a lower percentage of body weight as water and diminished thirst mechanism contribute to difficult intravenous access (Rosenthal, 2005).

and older adults have fragile veins, you should avoid sites that are easily moved or bumped, such as those on the dorsal surface of the hand. Venipuncture is contraindicated in a site that has signs of infection, infiltration, or thrombosis. An infected site is red, tender, swollen, and possibly warm to the touch, and exudate may be present. An infected site is not used because of the danger of introducing bacteria from the skin surface into the bloodstream. Arms on the side of a mastectomy and extremities with an arteriovenous graft or fistula for dialysis should be avoided. It is important to place intravenous devices at the most distal point when possible as this allows for the use of proximal sites later if the patient needs a venipuncture site change. See Box 39-11 for guidelines related to the older adult.

Regulating the Infusion Flow Rate. After the intravenous infusion is secured and the line is patent, you must regulate the rate of infusion according to the prescriber's orders (Skill 39-2). An infusion rate that is too slow can lead to further cardiovascular and circulatory collapse in a critically ill patient. An intravenous fluid that is running too slowly can also clot

more easily. An infusion rate that is too rapid can result in FVE. Fluids that run by gravity are adjusted through use of a flow control or regulator clamp. Fluids infused by an electronic infusion device or rate controller are regulated by a mechanical mechanism set at the prescribed rate. Regardless of the device in use, the patient requires close monitoring to verify the correct infusion of the intravenous solution and to detect the occurrence of any complication.

Electronic infusion devices (EIDs) or infusion pumps are necessary when administering low hourly volumes (e.g., less than 20 mL/hour) and for patients who are at risk for volume overload, such as neonatal, pediatric, and geriatric patients. In addition, when infusing high volumes of intravenous fluids (more than 150 mL/hour) to patients with impaired renal clearance, older adults, or children, or when infusing drugs or intravenous fluids that require specific hourly volumes, electronic infusion devices permit accurate infusion. Electronic infusion devices deliver the infusion via positive pressure and have become standard in most settings. Recent advances in infusion technology have resulted in a variety of devices available for use to ensure accurate delivery.

Many devices have operating and programming capabilities that allow for single- and multiple-solution infusions at different rates. A variety of detectors and alarms respond to air in intravenous lines, completion of infusion, high and low pressure, low battery power, occlusion, and the inability to deliver at a preset rate.

safety alert An anti-free-flow safeguard (preventing bolus infusion in the event of machine malfunction) is an important element of an electronic infusion device and is required. The manufacturer's recommendations for specific device features should always be checked.

Patency of the intravenous needle or catheter means that the tip of the needle or catheter has no clots and that the catheter or needle tip is not against the vein wall. A blocked catheter or needle can affect the rate of infusion of the intravenous fluids. Intravenous flow rates can also be affected by infiltration, a knot or kink in the tubing, the height of the solution, a restrictive intravenous dressing, and the position of the patient's extremity. One way to assess patency is by lowering the intravenous bag below the level of the intravenous insertion site and observing for a blood return; however, this method does not confirm patency. If no blood return occurs and fluid does not flow easily from the drip chamber when the roller clamp is opened, you should assess potential causes: a clot may be occluding the cannula of the intravenous catheter, the catheter tip may be occluded against the wall of the vein, or the intravenous dressing may be too tight, thereby impeding the flow. The tubing and area around the insertion site should be inspected for anything that could obstruct the flow of intravenous fluids. A knot or kink in the tubing can decrease the flow rate. Occasionally, the tubing is kinked under a dressing; remove the dressing to locate the problem. The patient may also occlude the tubing by lying or sitting on it. The flow rate frequently resumes after the tubing is straightened. The height of the intravenous bag can also affect flow rates. Raising the bag usually increases the rate because of increased hydrostatic pressure.

The position of the extremity, particularly at the wrist or elbow, can decrease flow rates. Occasionally, the use of an arm

► SKILL 39-2 Regulating Intravenous Flow Rates**Delegation Considerations**

In many provinces, regulating and monitoring intravenous therapy is included within the scope of practice for licensed and registered practical nurses. The skill of regulating intravenous therapy should not be delegated to unregulated care providers (UCPs). Refer to Skill 39-1 for important information to instruct the UCP.

Procedure**STEPS**

1. Check patient's medical record for correct solution, additives, and time of infusion. Usual order includes solution for 24 hours, usually divided into 2 or 3 L. Occasionally, intravenous order contains only 1 L to keep vein open (KVO). Order also indicates time over which each litre is to infuse.

Critical Decision Point: It is common for health care providers to write an abbreviated intravenous order such as "D5W with 20 mmol KCl 125 mL/hr continuous." This order implies that the intravenous fluid should be maintained at this rate until order has been written for intravenous line to be discontinued.

2. Perform hand hygiene. Observe for patency of intravenous line and needle or catheter.
 - A. Open drip regulator and observe for rapid flow of fluid from solution into drip chamber and then close drip regulator to prescribed rate.
3. Check patient's knowledge of how positioning of the intravenous site affects flow rate.
4. Verify with patient how venipuncture site feels (e.g., determine whether the patient is experiencing pain or burning sensation).
5. Have paper and pencil or calculator to calculate flow rate or use calculator.
6. Know calibration (drop factor) in drops per millilitre (gtt/mL) of infusion set:
 - A. **Microdrip:** 60 gtt/mL
 - B. **Macrodrop:** 15 gtt/mL or 10 gtt/mL depending on manufacturer (will state on package)

Equipment

- Watch or clock with a second hand
- Paper and pencil or calculator
- Intravenous electronic infusion controller or pump (optional)
- Volume control device (optional)
- Time indicator tape for gravity infusions

RATIONALE

- Use principles of drug administration to ensure correct fluids are given to correct patient.

- For fluid to infuse at proper rate, intravenous line and needle must be free of kinks, knots, and clots.
- Rapid flow of fluid into drip chamber indicates patency of intravenous line. Closing drip chamber to prescribed rate prevents fluid overload.
- Fosters patient participation in maintaining most effective position of arm with intravenous equipment.
- Includes patient in decision making. Pain or burning sensation may be early indication of phlebitis.
- The beginning student is unfamiliar with intravenous fluid rates and should use mathematical calculations to obtain correct rate.
- Microdrip tubing, also called pediatric tubing, universally delivers 60 gtt/mL and is used when small or very precise volumes are to be infused. However, different commercial parenteral administration sets for macrodrip tubing are available. Macrodrop tubing should be used when large quantities or fast rates are necessary.

Critical Decision Point: Know which company's infusion set your agency uses.

7. Calculate flow rate (hourly volume) of prescribed infusion. Flow rate mL/hr = total infusion (volume in mL)/hours of infusion (time to be infused).
Example: 1000 mL/8 hr = 125 mL/1 hr
 8. Read physician's orders and follow seven rights for correct solution and proper additives.
 9. Intravenous fluids are usually ordered by rate, such as 100 mL/hr. However, occasionally, intravenous fluids are ordered over a period of time, such as 1000 mL D5W with 20 mmol KCl over 8 hr.
- Once hourly rate has been determined, these formulas give correct flow rate.
 - Intravenous fluids are medications; following seven rights decreases chance of medication error.
 - Determines volume of fluid that should infuse hourly.

► SKILL 39-2 Regulating Intravenous Flow Rates—cont'd

10. Place adhesive or fluid indicator tape on intravenous bottle or bag next to volume markings (see Step 10 illustration).

- Time taping intravenous bag gives visual cue as to whether fluids are being administered over correct period of time. Time tapes may be required for all intravenous infusions, including those on therapies infused via electronic infusion devices (EIDs). Check agency policy.

Critical Decision Point: Do not use felt-tipped pens or permanent markers on intravenous bags made of polyvinyl chloride because ink could contaminate the solution (Millam & Hadaway, 2003).

11. Select one of the following formulas to calculate minute flow rate (drops/min) on the basis of the drop factor of infusion set:

A. $\text{mL/hr} / 60 \text{ min} = \text{mL/min}$ and $\text{Drop factor} \times \text{mL/min} = \text{drops/min}$

B. Alternative: $\text{mL/hr} \times \text{drop factor} / 60 \text{ min} = \text{drops/min}$
Using formula B above, calculate minute flow rate for bottle 1: 1000 mL with 20 mmol KCl

Microdrip:

$$125 \text{ mL/hr} \times 60 \text{ gtt/mL} = 7500 \text{ gtt/hr}$$

$$7500 \text{ gtt} \div 60 \text{ minutes} = 125 \text{ gtt/min}$$

Macrodrop:

$$125 \text{ mL/hr} \times 15 \text{ gtt/mL} = 1875 \text{ gtt/hr}$$

$$1875 \text{ gtt} \div 60 \text{ minutes} = 31 \text{ gtt/min}$$

12. Establish flow rate by counting drops in drip chamber for one minute by watch; then adjust roller clamp to increase or decrease rate of infusion (see Step 12 illustration).

- Formulas compute correct flow rate over a minute.
- Total volume $\times$ drop factor / infusion time in minutes
- Volume is multiplied by drop factor, and the product is divided by time (in minutes).
- When using microdrip, mL/hr always equals gtt/min.
- Determines whether fluids are administered too slowly or too quickly.

Step 10 Intravenous fluid bag with time tape.

Step 12 Counting intravenous drip rate.

13. Follow manufacturer's procedure for electronic infusion devices (EID).

- Infusion devices are recommended for minimizing risks associated with VAD (Lavery & Smith, 2007).

Continued

► SKILL 39-2 Regulating Intravenous Flow Rates—cont'd

video

Most pumps require you to begin by placing the intravenous infusion tubing within ridges of control box in direction of flow (i.e., portion of tubing nearest intravenous bag at top and portion of tubing nearest patient at bottom) (see Step 13B illustrations). Required drops per minute or volume per hour and volume to be infused are selected. Open rate control clamp and press start button.

- Infusion pumps move fluid by compressing and milking intravenous tubing, thus propelling fluid through tubing.
- Rate control clamp should be open completely while infusion controller or pump is in use.

Step 13 A, Place infusion tubing within ridges of pump. B, Press start button to begin infusion.

Critical Decision Point: Special infusion tubing is required for some pumps (check manufacturer's directions).

- A. Monitor infusion rates and intravenous site for complications according to agency policy.
 - B. Assess patency and integrity of system when alarm sounds.
14. Follow this procedure for volume control device:
 - A. Place volume control device (see Step 14A illustration) between intravenous bag and insertion spike of infusion set using sterile technique.
- Infusion controllers or pumps are not infallible and do not replace frequent, accurate nursing assessments. Infusion pumps may continue to infuse intravenous fluids after an infiltration has begun. All EIDs must have free-flow protector device.
 - Alarm indicates that electronic eye has not noted precise number of drops from drip chamber, the solution bag or bottle is empty, or flow is obstructed (e.g., kink in tubing, closed drip regulator, infiltrated or clotted needle, or air in the tubing).
 - Reduces risk of sudden increase in fluid volume.

Step 14A Volume control device.

► SKILL 39-2 Regulating Intravenous Flow Rates—cont'd

- B.** Place two hours of fluid allotment into chamber device.
- C.** Assess system at least hourly; add fluid to volume control device. Regulate flow rate.
15. Record name of solution, rate of infusion, drops/minute, and mL/hour in nurses' notes or flow sheet every four hours or according to patient's condition and to agency policy. Immediately record in nurses' notes or flow sheet any new intravenous fluid rates. Document use of any EID or controlling device and number on that device.
 16. Observe patient for response to therapy. Refer to Skill 39-1, Steps 42 and 44.
 17. Evaluate infusion site for signs of infiltration, inflammation, clot in catheter, or kink or knot in infusion tubing.
- Prevents intravenous line from running dry if nurse does not return in exactly 60 minutes. In addition, if an accidental increase in flow rate occurs, patient receives at most only a two-hour allotment of fluid.
 - Maintains patency of system.
 - Prompt and accurate documentation informs interdisciplinary collaboration.
 - Signs and symptoms of dehydration or overhydration warrant changing rate of fluid infused.
 - Prevents decrease in or cessation of flow rate.

Unexpected Outcomes

Sudden infusion of large volume of solution, with symptoms of dyspnea, crackles in lungs, and increased urine output, indicating fluid overload

Intravenous fluid bag runs empty, with subsequent loss of intravenous line patency

Related Interventions

- Slow infusion to KVO rate and notify physician immediately. New intravenous orders will be required. Patient may require diuretics.
- Intravenous therapy will be restarted.
- The intravenous infusion is slower than ordered.
- Check patient for positional change that might affect infusion rate, height of intravenous bag, kinking of tubing.
- An infiltration may be developing at intravenous site. Check condition of site.
- If volume infused is deficient, consult physician for new order to provide necessary fluid volume.

Reporting

- At change of shift or when leaving on break, report rate of infusion to nurse in charge or next nurse assigned to care for patient.

Home Care Considerations

- Ensure that patient is able and willing to operate the EID (if applicable) and administer intravenous therapy or that a reliable caregiver or nursing support personnel is at home to provide this intravenous therapy care.
- Teach patient and primary caregiver to time drops per minute using watch with second hand.
- Ensure proper EID function and that electrical outlets are functioning properly and grounded and infusion device has backup power, if required by type of infusate.
- Teach patient and caregiver alarms and how to troubleshoot them.
- Provide patient and caregiver with a phone number that can be accessed 24 hours a day.

board helps keep the joint extended (Figure 39-14). The arm board also provides some protection to the intravenous site and tubing. Most often it is preferred to have an IV catheter inserted in a new site rather than relying on a site that causes problems. However, before discontinuing the infusion hampered by an extremity position, you should start the infusion in another site to verify that the patient has other accessible veins.

Sudden increases can occur accidentally. For example, a restless patient may loosen the roller clamp with a sudden movement and increase the flow rate, or the flow rate may be accidentally increased if the patient ambulates. Some IV catheters are positional in the patient's vein. A sudden increase in the intravenous infusion rate causes a rapid increase in vascular volume, which can make the patient critically ill or even cause death. EID and volume control devices are designed to prevent sudden changes in infusion rate.

Figure 39-14 Intravenous arm board.

Figure 39-15 Potential sites for contamination of an intravenous device.

Maintaining the System. After the intravenous line is in place and the flow rate is regulated, you must maintain the system. Observe agency policy regarding the maintenance of intravenous lines. Line maintenance is achieved by (1) keeping the system sterile; (2) changing solutions, tubing, and site dressings; and (3) assisting the patient with self-care activities so as not to disrupt the system.

You play an important role in maintaining the integrity of an intravenous line to prevent infection from developing. Knowledge of potential sites for contamination informs your practice (Figure 39-15). This begins with thorough hand hygiene before and after handling any component of the intravenous system.

The integrity of the intravenous system must always be maintained. Never disconnect tubing because it becomes

tangled or because it might be more convenient in positioning or moving a patient or applying a gown. If a patient needs more room to manoeuvre, extension tubing can be added to an intravenous line. However, the use of extension tubing should be kept to a minimum as each connection of tubing provides an opportunity for contamination. Stopcocks for connecting more than one solution to a single intravenous site are sources of contamination and should be avoided (INS, 2006). Whenever an intravenous line is disconnected from a stopcock, the port should be plugged with a sterile cap. A port should never remain exposed to air because of the risk of contamination. A new administration set should be exchanged with the subsequent fluid change.

Intravenous tubing also contains injection ports through which adapters can be inserted for medication injections. Gillies et al. (2008) recommend that intravenous tubing may be used for up to 96 hours without increasing chance of infection if it does not contain lipids, blood, or blood products. Needleless injection ports reduce the risk of needle-stick injury and reduce contamination, thereby promoting patient safety when connecting, accessing, or removing intravenous equipment (Casey & Elliot, 2007a, 2007b). This risk is further minimized by using alcohol-chlorhexidine gluconate solution or povidone-iodine for cleansing the port both before and after use (Casey & Elliott, 2007b). Kaler and Chinn (2007) recommend using pressure and friction with a cleansing swab for 15 seconds for preparation of a needleless port. Patients receiving intravenous therapy over several days will require a change of solutions. It is important to organize tasks so that this can be done in plenty of time before the solution empties and the cannula becomes clotted. Many agencies have policies regarding the “hang time” of intravenous fluids. Rickard et al. (2009) found no need to routinely replace IV fluid containers and recommend further research to establish set time points for replacing IV fluid containers. Skill 39-3 reviews steps for changing intravenous solutions.

Text continued on p. 983

► SKILL 39-3 Maintenance of Intravenous System

Delegation Considerations

In many provinces, this skill is included within the scope of practice for licensed and registered practical nurses. The skill of changing intravenous solutions and tubing should not be delegated to unregulated care providers (UCPs). UCPs may be delegated the tasks of collecting supplies, assisting with comfort measures, and distracting the patient during the procedure.

Equipment

Intravenous Infusion

- Bottle or bag of intravenous solution as ordered by physician
- Time tape
- Infusion tubing and tubing label
- Filter (size appropriate to solution) and extension tubing (if necessary)

Intermittent Saline Lock

- Injection cap, loop, or short extension tubing (if necessary)

Normal Saline Flush

- Syringe filled with normal saline
- 2 sterile 2 × 2 (5 cm × 5 cm) gauze pads
- Tape
- Disposable gloves

Discontinuation of Intravenous Line

- Disposable gloves
- Alcohol swabs
- Sterile 2 × 2 (5 cm × 5 cm) gauze
- Tape

► SKILL 39-3 Maintenance of Intravenous System—cont'd**Procedure****STEPS****Changing Intravenous Solution**

1. Check physician's orders.
2. If order is written for keep-vein-open (KVO) or to keep open (TKO), contact physician for clarification of the rate of the infusion. Note date and time when solution was last changed.
3. Determine the compatibility of all intravenous fluids and additives by consulting appropriate literature or the pharmacy.
4. Determine patient's understanding of need for continued intravenous therapy.
5. Assess patency of current intravenous access site.
6. Have next solution prepared and accessible at least one hour before needed. Check that solution is correct and properly labelled. Check solution expiration date and for presence of precipitate and discolouration.
7. Prepare to change solution when less than 50 mL of fluid remains in bottle or bag or when a new type of solution is ordered.
8. Prepare patient and family by explaining the procedure, its purpose, and what is expected of patient.
9. Be sure drip chamber is at least half full.
10. Perform hand hygiene.
11. Prepare new solution for changing. If using plastic bag, remove protective cover from intravenous tubing port. If using glass bottle, remove metal cap and metal and rubber discs.
12. Move roller clamp to stop flow rate.
13. Remove old intravenous fluid container from intravenous pole.
14. Quickly remove spike from old solution bag or bottle and, without touching tip, insert spike into new bag or bottle.

RATIONALE

- Ensures that correct solution will be used. Intravenous therapy requires the seven rights of medication administration.
- Orders for KVO do not provide complete information and can result in fluid overload or deficit and electrolyte imbalance. A KVO order should contain a specific infusion rate (INS, 2006). Refer to agency policy. Intravenous tubing and solution should be changed at the same time.
- Incompatibilities may lead to precipitate formation and can cause physical, chemical, and therapeutic patient changes. Precipitation may occlude patency of catheter.
- Reveals need for patient instruction.
- If patency is occluded, a new intravenous access site may be needed. Notify physician.
- Adequate planning reduces risk of clot formation in vein caused by empty intravenous bag. Checking prevents medication error.
- Prevents air from entering tubing and vein from clotting from lack of flow.
- Decreases anxiety and promotes cooperation.
- Provides fluid to vein while bag is changed.
- Reduces transmission of microorganisms.
- Permits quick, smooth, and organized change from old to new solution.
- Prevents solution remaining in drip chamber from emptying while changing solutions.
- Brings work to nurse's eye level.
- Reduces risk of solution in drip chamber running dry and maintains sterility.

Critical Decision Point: If spike is contaminated, a new intravenous tubing set is required.

15. Hang new bag or bottle of solution on intravenous pole.
 16. Check for air in tubing. If bubbles form, they can be removed by closing the roller clamp, stretching the tubing downward, and tapping the tubing with the finger (the bubbles rise in the fluid to the drip chamber; see Step 16 illustration). For larger amounts of air, swab injection port below the air with alcohol and allow to dry. Connect a syringe to this port and aspirate the air into the syringe. Reduce air in tubing by priming slowly instead of allowing a wide-open flow.
- Gravity assists with delivery of fluid into drip chamber.
 - Reduces risk of air embolus. Use of an air-eliminating filter also reduces this risk.

Continued

► SKILL 39-3 Maintenance of Intravenous System—cont'd

17. Make sure drip chamber is one-third to one-half full. If the drip chamber is too full, pinch off tubing below the drip chamber, invert the container, squeeze the drip chamber (see Step 17 illustration), hang up the bag, and release the tubing.

Step 16 Tap tubing to cause air bubbles to rise up to drip chamber.

Step 17 Pinch tubing, invert chamber, and squeeze drip chamber to remove a portion of fluid. **Source:** Courtesy Darlaine Jantzen.

18. Regulate flow to prescribed rate.
19. Mark time on label tape and place on bag. Do not use felt-tipped pens or permanent markers on intravenous bags.
20. Observe patient for signs of overhydration or dehydration to determine response to intravenous fluid therapy.
21. Observe intravenous system for patency and development of complications (e.g., infiltration or phlebitis).

Changing Intravenous Tubing

22. Determine when new infusion set is needed:
- A. Agency policy will indicate frequency of routine change for intravenous administration sets and saline flush tubing.
 - B. Puncture of infusion tubing requires immediate change.
 - C. Contamination of tubing requires immediate change.
 - D. Occlusions in existing tubing can occur after infusion of packed red blood cells, whole blood, albumin, or other blood components.
23. Prepare patient and family by explaining the procedure, its purpose, and what is expected of patient.
24. Perform hand hygiene.
25. Open new infusion set, keeping protective coverings over infusion spike and distal adapter. Secure all junctions with Luer-Loks, clamping devices, or threaded devices.
26. Apply nonsterile, disposable gloves.
- Reduces risk of air entering tubing.
 - Maintains measures to restore fluid balance and deliver intravenous fluid as ordered.
 - Ink from markers may leach through polyvinyl chloride containers.
 - Provides ongoing evaluation of patient's fluid and electrolyte status.
 - Provides ongoing evaluation of intravenous system.
 - Note that usually the tubing and the bag, and even the site, are changed at the same time. (Refer to Steps 13–22, 33, and 34, to change bag and tubing.)
 - Recent evidence (Gillies et al., 2008) recommends up to 96 hours for tubing changes.
 - Punctured tubing results in fluid leakage and bacterial contamination.
 - Contamination of tubing allows entry of bacteria into patient's bloodstream.
 - Whole blood or blood component product can occlude or partially occlude tubing because viscous solutions adhere to walls of tubing and decrease the size of the lumen.
 - Decreases anxiety, promotes cooperation, and prevents sudden movement of extremity, which could dislodge intravenous needle or catheter.
 - Reduces transmission of microorganisms.
 - Provides nurse with ready access to new infusion set and maintains sterility of infusion set.
 - Reduces risk of exposure to HIV, hepatitis, and other bloodborne pathogens.

SKILL 39-3 Maintenance of Intravenous System—cont'd

27. If catheter hub is not visible, remove intravenous dressing while maintaining stability of catheter. If transparent dressing has to be removed, place small piece of sterile tape across hub temporarily to anchor catheter during disconnection. Do not remove tape securing catheter to skin with gauze dressing.
 28. For intravenous continuous infusion:
 - A. Move roller clamp on new intravenous tubing to closed position.
 - B. Slow rate of infusion by regulating drip rate on old tubing. Be sure rate is at KVO rate.
 - C. Compress and fill drip chamber of old tubing.
 - D. Remove intravenous container from pole, invert container, and remove old tubing from container. Carefully hold container while hanging or taping drip chamber on intravenous pole 1 m above intravenous site.
 - E. Place insertion spike of new tubing into old solution bag opening and hang solution bag on intravenous pole.
 - F. Compress and release drip chamber on new tubing; fill drip chamber one-third to one-half full.
 - G. Slowly open roller clamp, remove protective cap from needle adapter (if necessary), and flush new tubing with solution. Replace cap.
 - H. Turn roller clamp on old tubing to closed position.
 29. To connect to a saline lock:
 - A. If a loop or short extension tubing is needed because of an awkward intravenous site placement, use sterile technique to connect the new injection cap to the loop or tubing.
 - B. Swab injection cap with recommended solution for 15 seconds. Insert syringe with 1 to 3 mL saline and inject through the injection cap into the loop or short extension tubing (see Step 29B illustrations). Connect tubing to injection cap.
- Hub must be accessible to provide smooth transition when removing old and inserting new tubing.
 - Prevents spillage of solution after bag or bottle is spiked.
 - Prevents complete infusion of solution that remains in tubing, which can increase risk of occlusion of intravenous catheter or needle.
 - Provides surplus of fluid in drip chamber so enough fluid is available to maintain intravenous patency while changing tubing.
 - Fluid in drip chamber will run slowly to keep catheter patent.
 - Permits flow of fluid from solution into new infusion tubing.
 - Allows drip chamber to fill and promotes rapid, smooth flow of solution through new tubing.
 - Removes air from tubing and replaces it with fluid.
 - Prevents spillage of fluid as tubing is removed from needle hub.
 - Removes air to prevent introduction into the vein.

Step 29B A, Inject saline into injection cap. B, Connect to saline lock extension tube.

30. To change (continuous or extension set) tubing at the hub, stabilize hub of catheter and apply pressure over vein just above catheter tip at least 3 cm above insertion site. Gently disconnect old tubing from catheter hub. Maintain stability of hub and quickly insert adapter of new tubing or saline lock into hub.
 31. Open roller clamp on new tubing. Allow solution to run rapidly for 30 to 60 seconds.
 32. Regulate intravenous drip according to physician's orders and monitor rate hourly.
- It is important to maintain asepsis at the catheter hub; therefore, place an alcohol swab or sterile gauze beneath the hub.
 - Prevents accidental displacement of catheter or needle.
 - Prevents clot formation in catheter or needle and backflow of blood.
 - Permits intravenous solution to enter catheter to prevent catheter occlusion.
 - Maintains infusion flow at prescribed rate.

Continued

► SKILL 39-3 Maintenance of Intravenous System—cont'd

33. Apply new dressing, if needed.
34. Discard old tubing in proper container.
35. Remove and dispose of gloves. Perform hand hygiene.
36. Evaluate flow rate and observe connection site for leakage.

Discontinuing Peripheral Intravenous Access

37. Check physician's order for discontinuation of intravenous therapy.
 38. Explain procedure to patient. Explain that affected extremity must be held still and how long procedure will take.
 39. Perform hand hygiene and apply disposable gloves.
 40. Turn intravenous tubing roller clamp to closed position. Remove tape securing tubing.
 41. Remove intravenous site dressing and tape while stabilizing catheter.
 42. With dry gauze or alcohol swab held over site, apply light pressure and withdraw the catheter, using a slow steady movement, keeping the hub parallel to the skin (see Step 42 illustration).
- Reduces risk of bacterial infection from skin.
 - Reduces accidental transmission of microorganisms.
 - Reduces transmission of microorganisms.
 - Maintains prescribed rate of flow of intravenous fluid and determines if fit is secure.
 - Order is required for discontinuation of fluids or medication.
 - Minimizes patient's anxiety and discomfort.
 - Reduces transmission of microorganisms.
 - Movement of catheter will cause discomfort.
 - Changing the angle of the catheter inside the vein could cause additional vein irritation, increasing the risk of postinfusion phlebitis.

Step 42 Remove catheter slowly, keeping it parallel to the vein.

Critical Decision Point: If patient has received anticoagulants (e.g., low-dose aspirin, warfarin sodium [Coumadin], heparin) or has a low platelet count, apply steady pressure for 5 to 10 minutes and assess bleeding.

43. Apply pressure to the site for two to three minutes, or until no further bleeding is noted, using the dry, sterile gauze pad. Secure with tape.
 44. Inspect the catheter for intactness, noting tip integrity and length.
 45. Discard used supplies.
 46. Remove and discard gloves and perform hand hygiene.
 47. Instruct patient to report any redness, pain, drainage, or swelling that may occur after catheter removal.
- Dry pad causes less irritation to the puncture site. Subcutaneous hematoma is a common complication. When needle is removed, vein wall contracts to stop bleeding.
 - Tips of catheter can break off, causing an embolus, an emergency situation. Notify physician if tip is broken.
 - Postinfusion phlebitis may occur within 48 to 96 hours after catheter removal.

Unexpected Outcomes

Incorrect flow rate; patient receives too little or too much fluid

Decreased or absent flow of intravenous fluid

Related Interventions

- Readjust infusion rate to ordered rate; evaluate patient for adverse effects; notify physician.
- Assess intravenous infusion system for patency.
- Recalibrate drip rate on new tubing.
- Assess intravenous site for infiltration.

Recording and Reporting

- Record changing of tubing and solution on patient's record. A special parenteral therapy flow sheet may be used.
- Place a piece of tape or preprinted label with the date and time of tubing change and attach to tubing below the level of drip chamber.

Home Care Considerations

- Emphasize to patient and family the importance of changing solutions when intravenous tubing still contains fluid.

The dressings over intravenous sites are applied to reduce the entrance of bacteria into the insertion site. The two forms of dressings are transparent and gauze. Transparent dressings reliably secure the intravenous device, allow continuous visual inspection of the intravenous site, become less easily soiled or moistened, and require less frequent changes than standard gauze. Intravenous dressings should be routinely changed as per agency policy (Skill 39-4).

To prevent the accidental disruption of an intravenous system, you may need to assist the patient with hygiene, comfort measures, meals, and ambulation. Using a gown specifically made with snaps along the top sleeve seam helps facilitate changing the gown without disturbing the venipuncture site. Regular gowns are changed as follows:

1. Remove the sleeve of the gown from the arm without the intravenous line, maintaining the patient's privacy.
2. Remove the sleeve of the gown from the arm with the intravenous line.
3. Remove the intravenous solution container from its stand and pass it and the tubing through the sleeve. (If this involves removing the tubing from an intravenous electronic infusion device, use the roller clamp to slow the infusion to prevent the accidental infusion of a large volume of solution or medication.)
4. Place the intravenous solution container and tubing through the sleeve of the clean gown and hang it on its stand. (If the intravenous line is connected to an electronic infusion device, open the roller clamp. Turn on the pump.)

► SKILL 39-4 Changing a Peripheral Intravenous Dressing

Delegation Considerations

In many provinces, the skill of changing a peripheral intravenous dressing is included within the scope of practice for licensed and registered practical nurses. This skill should not be delegated to unregulated care providers (UCPs). UCPs may be delegated the tasks of collecting supplies, assisting with comfort measures, and distracting the patient during the procedure.

Equipment

- Antiseptic swab stick (chlorhexidine, povidone-iodine, or 70% alcohol, as recommended by the agency)
- Adhesive remover (if needed)
- Strips of nonallergenic sterile tape for use underneath the dressing
- Disposable gloves
- *For gauze dressing:*
 - Sterile 2 × 2 (5 cm × 5 cm) gauze pad OR
 - Sterile 4 × 4 (10 cm × 10 cm) gauze pad
- *For transparent dressing:*
 - Sterile transparent dressing

Procedure

STEPS

1. Determine when dressing was last changed. Many institutions require that the nurse records the date and time on the dressing when the device is first placed.
2. Perform hand hygiene. Observe present dressing for moisture and intactness.
3. Observe intravenous system for proper functioning or complications: kinks in infusion tubing or intravenous catheter. Palpate the catheter site through the intact dressing for inflammation or subjective complaints of pain or burning sensation.
4. Inspect exposed catheter site for swelling or blanching and other signs of infiltration.
5. Assess patient's understanding of need for continued intravenous infusion.
6. Explain procedure and purpose to patient and family. Explain that affected extremity must be held still and how long procedure will take.
7. Apply disposable gloves.
8. Remove tape, gauze, or transparent dressing from old dressing one layer at a time, leaving tape (if present) that secures intravenous catheter in place. Be cautious if catheter tubing becomes tangled or attached to dressing. When removing transparent dressing, hold catheter hub and tubing with nondominant hand.
9. Observe insertion site for signs and symptoms of infection (redness, swelling, and exudate). If present, remove catheter and insert a new intravenous line in another site.

RATIONALE

- Provides information regarding length of time present dressing has been in place. The Centers for Disease Control recommends that, whenever possible, peripheral intravenous dressings should be scheduled when intravenous system is changed.
- Moisture is a medium for bacterial growth and renders dressing contaminated.
- Unexplained decrease in flow rate requires investigation of placement and patency of the intravenous catheter. Pain can be associated with both phlebitis and infiltration.
- Indicates fluid infusing into surrounding tissues. Will require removal of intravenous catheter.
- Determines need for patient instruction.
- Decreases anxiety, promotes cooperation, and gives patient time frame around which personal activities can be planned.
- Reduces transmission of microorganisms.
- Prevents accidental displacement of catheter or needle.
- Presence of infection or complication indicates need to remove VAD at current site.

Continued

► SKILL 39-4 Changing a Peripheral Intravenous Dressing

10. If infiltration, phlebitis, or clot occurs or if ordered by physician, stop infusion and discontinue intravenous therapy. Restart new intravenous line if continued therapy is necessary. Place moist, warm compress over area of phlebitis.
 11. If intravenous fluid is infusing properly, gently remove any tape securing catheter. Stabilize needle or catheter with one hand. Use adhesive remover to cleanse skin and remove adhesive residue, if needed.
 12. Stabilize catheter at all times with one finger over catheter until tape or dressing is replaced.
 13. Using circular motion, cleanse peripheral intravenous insertion site with antiseptic swab starting at insertion site and working outward, creating concentric circles (see Step 13 illustration). Allow swab solution to air-dry completely.
- Exposes venipuncture site. Stabilization prevents accidental displacement of catheter or needle. Adhesive residue decreases ability of new dressing to adhere tightly to skin.
 - Prevents decannulation from vein.
 - Circular motion prevents cross-contamination from skin bacteria near venipuncture site. Antiseptics may include chlorhexidine, povidone-iodine, and alcohol. RNAO (2005) recommends 2% chlorhexidine-based solution. If antiseptic agents are used in combination, allow each to dry separately.

Step 13 Cleanse peripheral insertion site.

Critical Decision Point: Do not tape over connection of access tubing or port to intravenous catheter.

14. Apply new transparent or gauze dressing (see Skill 39-1, Step 34A or 34B).
 15. Remove and discard gloves.
 16. Anchor intravenous tubing with additional pieces of tape. When using transparent polyurethane dressing, minimize the tape placed over dressing.
 17. Place insertion date, date and time of dressing change, size and gauge of catheter, and your initials directly on dressing. Apply arm board, commercial housing device, or both if site is affected by joint motion.
 18. Discard used equipment and perform hand hygiene.
 19. Observe functioning and patency of intravenous system in response to changing dressing.
 20. Monitor patient's body temperature.
- Ensures protection of intravenous site and reduces chance of infection.
 - Prevents accidental displacement of intravenous needle or catheter or separation of intravenous tubing from needle adapter.
 - Documents dressing change.
 - Reduces transmission of microorganisms.
 - Validates that intravenous line is patent and functioning correctly.
 - Elevated temperature indicates an infection that may be associated with bacterial contamination of the venipuncture site.

Unexpected Outcomes

Infiltration of intravenous catheter, as evidenced by decreased flow rate or edema, pallor, or decreased temperature around insertion site

Accidental removal of intravenous catheter or needle
Elevated body temperature

Red, edematous, or painful insertion site or presence of exudates, indicating infection at venipuncture site

Related Interventions

- Stop infusion and discontinue intravenous therapy. Restart new intravenous line in other extremity if continued therapy is necessary.
- Elevate affected extremity.
- Restart intravenous infusion if continued therapy is needed.
- Notify physician. Intravenous line may be removed and restarted. Patient will be evaluated for source of infection.
- Discontinue intravenous infusion. Antibiotic therapy may begin.
- Apply warm, moist compress to area of inflammation.

Recording and Reporting

- Record appearance of intravenous site, type of dressing, and status of intravenous fluid infusion.
- A special parenteral fluid flow sheet may be used for recording.

Figure 39-16 IV House protective device. **Source:** Courtesy IV House, St Louis, MO.

5. Place the arm with the intravenous line through the gown sleeve.
6. Place the arm without the intravenous line through the gown sleeve. (Breaking the integrity of an intravenous line to change a gown leads to contamination.)

Protective devices designed to prevent accidental dislodgement of an intravenous catheter (Figure 39-16) are now available. The device fits comfortably around a patient's hand or arm and provides a plastic shield to cover the intravenous device. Protective devices extend the time a catheter remains in the vein and minimize repeated venipuncture (Rosenthal, 2005).

The patient with an arm or a hand infusion is able to walk, unless contraindicated. A portable intravenous pole (a standard intravenous pole with wheels) is needed. Help the patient get out of bed and place the pole next to the involved arm. The patient is instructed to hold on to the pole and push it while walking. Assess the equipment to make sure that the intravenous bag is at the proper height, that the tubing is not tense, that the flow rate is correct, and that the tubing does not get contaminated. Instruct the patient to report any blood in the tubing, a stoppage in the flow, or increased discomfort. Intravenous medications, especially antibiotics and potassium, can cause discomfort and burning sensations at the intravenous site. Although discomfort may be relieved by repositioning the extremity, the source of discomfort must always be carefully evaluated and may necessitate starting a new intravenous line in a larger vein.

Complications of Intravenous Therapy. An **infiltration** occurs when intravenous fluids enter the surrounding space around the venipuncture site (see Table 39-8). This is manifested as swelling (from increased tissue fluid) and pallor and coolness (caused by decreased circulation) around the venipuncture site. Fluid may be flowing through the intravenous line at a decreased rate or may have stopped flowing. Pain may also be present and usually results from edema. This pain increases proportionately as the infiltration continues.

When infiltration occurs, the infusion must be discontinued, and if intravenous therapy is still necessary, a new catheter is inserted into a vein in another extremity. To reduce discomfort

and edema, raise the extremity, which promotes venous drainage. Wrapping the extremity in a warm, moist towel for 20 minutes while keeping it elevated on a pillow also promotes venous return, increases circulation, and reduces pain and edema. This can be repeated three to four times per day until resolved. Infiltration of medications that cause extravasation require specific care, outlined by institutional policy.

Phlebitis is inflammation of the vein. Selected risk factors for phlebitis include the type of catheter material, chemical irritation of additives and drugs given intravenously (e.g., antibiotics), the rate of the medication administration, the skill of the individual inserting the catheter, and the anatomical position of the catheter. Signs and symptoms may include pain, edema, erythema, increased skin temperature over the vein, and, in some instances, redness travelling along the path of the vein (INS, 2006). Dehydration may also be a contributing factor because of the increase in blood viscosity.

When phlebitis develops, the intravenous line must be discontinued and a new line inserted in another vein. Warm, moist heat on the site of phlebitis can offer some relief to the patient. Phlebitis can be dangerous because blood clots (thrombophlebitis) can occur and in some cases may result in emboli. This may result in permanent damage to veins and in prolonging the patient's hospitalization.

Bleeding can occur around the venipuncture site during the infusion or through the catheter needle or tubing if these become inadvertently disconnected. Bleeding is common in patients who have received heparin or who have a bleeding disorder (e.g., leukemia or thrombocytopenia). If bleeding occurs around the venipuncture site and the catheter is within the vein, a pressure dressing may be applied over the site to control the bleeding. Bleeding from a vein is usually a slow, continuous seepage and is not serious.

Discontinuing Intravenous Infusions. Discontinuing an infusion is necessary after the prescribed amount of fluid has been infused, when an infiltration occurs, if phlebitis is present, or if the infusion catheter or needle develops a clot at its tip. Refer to Skill 39-3, Steps 38 to 48.

Blood Replacement. Blood replacement or transfusion is the intravenous administration of whole blood or a component such as plasma, packed red blood cells (RBCs), or platelets. The objectives for blood transfusions include the following: (1) to increase circulating blood volume after surgery, trauma, or hemorrhage; (2) to increase the number of RBCs and to maintain hemoglobin levels in patients with severe anemia; and (3) to provide selected cellular components as replacement therapy (e.g., clotting factors, platelets, albumin).

Blood Groups and Types. The most important grouping for transfusion purposes is the ABO system, which includes A, B, O, and AB blood types. The determination of blood groups is based on the presence or absence of A and B RBC antigens. Individuals with A antigens, B antigens, or no antigens belong to groups A, B, and O, respectively. The person with A and B antigens has AB blood. Individuals with type A blood naturally produce anti-B antibodies in their plasma. Similarly, individuals with type B blood naturally produce anti-A antibodies. An individual with type O blood has neither type A nor type B antigen and thus is considered a universal blood donor. Individuals with type AB blood produce neither antibody, which is why they can be universal recipients and receive any type of blood (Table 39-10). If blood that is mismatched with the patient's blood is transfused, a **transfusion reaction** occurs. The transfusion reaction is an antigen-antibody reaction and

► TABLE 39-10 Blood Groups and Compatibility

Blood Type	Antigens of Red Blood Cell	Able to Donate	Serum (Plasma) Antibodies	Able to Receive From
A	A	A, AB	Anti-B	A, O
B	B	B, AB	Anti-A	B, O
AB	A and B	AB	None	A, B, AB, O
O	None	A, B, AB, O	Anti-A and anti-B	O

can range from a mild response (e.g., faintness, dizziness) to severe anaphylactic shock, which can be life-threatening (Davis et al., 2005–2006).

Another consideration when matching for blood transfusions is the Rh factor, which is an antigenic substance in the erythrocytes. A person with the factor is Rh positive, and a person without it is Rh negative. Blood must be matched for Rh factor as well as ABO grouping. Rh negative people must receive only Rh negative blood, whereas Rh positive people can receive either Rh negative or Rh positive blood.

Autologous Transfusion. Autologous transfusion or auto-transfusion is the collection of a patient's own blood. The blood for an autologous transfusion can be obtained by preoperative donation up to five weeks before the planned surgery (e.g., heart, orthopedic, plastic, or gynecological). Patients can donate one to five units of their own blood, depending on the type of surgery and the ability of the patient to maintain an acceptable hematocrit. The blood will be tested for HIV and hepatitis B virus. Another way to collect blood for an autologous transfusion is during perioperative blood salvage (e.g., during vascular and orthopedic surgery, organ transplant surgery, and traumatic injuries). The blood that has been salvaged is then reinfused during the surgery. Blood can also be salvaged postoperatively from mediastinal and chest tube drainage and after joint and spinal surgery. Autologous transfusions decrease the risk of complications such as mismatched blood and exposure to bloodborne infectious agents.

Blood Transfusions. When transfusing blood or blood components, assessment is required before, during, and after the transfusion and for regulation of the transfusion because of the risk of allergic reactions. If the patient has an intravenous line in place, assess the venipuncture site for signs of infection or infiltration and patency. Determine the appropriate gauge of the intravenous catheter. A large catheter, such as 18 to 20 gauge, is recommended because blood is thicker and stickier than intravenous fluids. Blood administration tubing has an in-line filter (Figure 39-17). When priming blood administration tubing, 0.9% normal saline should be used to prevent hemolysis, or breakdown of RBCs.

Pretransfusion assessment also includes obtaining information from the patient. Ask whether the patient knows the reason for the blood transfusion and whether the patient has ever had a previous transfusion or transfusion reaction. A patient who has had a transfusion reaction is usually at no greater risk for a reaction with a subsequent transfusion. However, the patient may be anxious about the transfusion. Before giving a transfusion, explain the procedure and instruct the patient to report any side effects (e.g., chills, dizziness, or fever) once the transfusion begins. Check to be sure the patient has signed an informed consent form. Patients with certain cultural backgrounds may abstain from blood transfusions (Box 39-12).

Because of the danger of transfusion reactions, it is very important to use specific precautions in administering blood

Figure 39-17 Blood administration tubing.

* BOX 39-12 CULTURAL ASPECTS OF CARE

Preinfusion Assessments

When a patient's natural skin contains more melanin, it becomes more difficult to identify colour changes. Intravenous complications such as phlebitis and infiltration may not be easily detected. Patients with some cultural backgrounds have fear related to the donor process for blood. Patients with certain religious or personal beliefs may abstain from receiving blood transfusions or medications.

Implications for Practice

- Establish communication. Understand the values of family elders and know whom to speak with about intravenous procedures.
- Assess patients individually to determine their acceptance of or abstinence from therapeutic regimens.
- Appreciate patients' choice related to their therapy.
- Although some patients will abstain from receiving whole blood or packed RBCs, they will accept other blood products or alternatives.

Adapted from Rudnicke, C. (2003). Transfusion alternatives. *Journal of Infusion Nursing*, 26(3), 29.

or blood products. Obtain the patient's baseline vital signs before the transfusion begins. This allows you to determine when changes in vital signs occur, which can indicate that a transfusion reaction is developing. A thorough check of the blood product, the patient, and the compatibility of the blood

and the patient ensures that the patient receives the correct type of blood or blood product. Although you are not involved in the blood labelling process, you are responsible for determining that the blood delivered to the patient corresponds to the blood type listed in the patient's medical record. Two registered nurses or one registered nurse and a licensed practical nurse (see agency policy) must together check the label on the blood product against the patient's identification number, blood group, and complete name. If even a minor discrepancy exists, the blood should not be given and the blood bank should be notified immediately.

Initiation of a transfusion begins slowly to allow for the early detection of a transfusion reaction. Maintain the infusion rate, monitor for side effects, assess vital signs, and promptly record all findings. Stay with the patient during the first 15 minutes, the time when a reaction is most likely to occur. Continue to monitor the patient and obtain vital signs periodically during the transfusion as directed by agency policy.

The rate of transfusion is usually specified in the health care provider's orders. Ideally, a unit of whole blood or packed RBCs is transfused in two hours. This time can be lengthened to four hours if the patient is at risk for FVE. Beyond four hours, bacterial contamination of the blood is a risk (Davis et al., 2005–2006). When patients have a severe blood loss, such as with hemorrhage, they may receive rapid transfusions through a CVC. A blood-warming device is often necessary because the tip of the CVC lies in the superior vena cava, above the right atrium. Rapid administration of cold blood can result in cardiac dysrhythmia (Burgess, 2006).

The administration tubing used for RBCs should be discarded at four hours or after two units and should be discarded immediately following fractionated products, such as IVIG, clotting factors, and albumin (RNAO, 2005).

Transfusion Reactions. A transfusion reaction is a systemic response by the body to incompatible blood. Causes include RBC incompatibility or allergic sensitivity to the components of the transfused blood or to the potassium or citrate preservative in the blood. Several types of acute reactions can result from blood transfusions (Table 39-11). If a transfusion reaction is anticipated or suspected, monitor vital signs more frequently (see Table 39-11).

A second category of transfusion reactions includes diseases transmitted by infected blood donors who are asymptomatic. Diseases transmitted through transfusions are malaria, hepatitis, and AIDS. Because all units of blood collected must undergo serological testing and screening for HIV and hepatitis B virus, the risk of acquiring bloodborne infections from blood transfusions is reduced.

Circulatory overload is a risk when a patient receives large volumes of whole blood or packed RBC transfusions for massive hemorrhagic shock or when a patient with normal blood volume receives blood. Patients particularly at risk for circulatory overload are older adults and those with cardiopulmonary diseases.

Blood transfusion reactions are life-threatening, but prompt nursing intervention can maintain the patient's physiological stability.

- Do not turn off the blood and simply turn on the 0.9% normal saline that is connected to the Y-tubing infusion set. This would cause blood remaining in the Y-tubing to infuse into the patient. Even a small amount of mismatched blood can cause a major reaction.
- Notify the physician immediately.
- Remain with the patient, observing signs and symptoms and monitoring vital signs as often as every five minutes.
- Prepare to administer emergency drugs such as antihistamines, vasopressors, fluids, and steroids as per physician order or protocol.
- Prepare to perform cardiopulmonary resuscitation.
- Obtain a urine specimen and send it to the laboratory to determine the presence of hemoglobin as a result of RBC hemolysis.
- Save the blood container, tubing, attached labels, and transfusion record, and return them to the laboratory.

Restorative Care

After experiencing acute alterations in fluid, electrolyte, or acid-base balance, patients often require ongoing maintenance to prevent a recurrence of health alterations. Older adults and the chronically ill require special considerations to prevent complications from developing.

Home Intravenous Therapy. Intravenous therapy is often continued in the home setting for patients who are discharged from the hospital and have not completed their prescribed treatment or who require long-term therapy. Ideally, a family member will be available at home if the patient suddenly cannot manage the intravenous system or if a problem develops. A home care nurse will work closely with the patient and family to ensure that a sterile intravenous system is maintained and that complications are avoided or recognized promptly. Box 39-13 summarizes patient education guidelines for home intravenous therapy.

Nutritional Support. Most patients who have had electrolyte disorders or metabolic acid-base disturbances require ongoing nutritional support. Depending on the type of disorder, fluid or food intake may be encouraged or restricted (see Chapter 42). If patients are still responsible for meal preparation, they should learn to understand the nutritional content of foods and to read the labels of commercially prepared foods.

Medication Safety. Numerous medications and over-the-counter drugs contain components or create potential side effects that can alter fluid and electrolyte balances. Patients with chronic disease who are receiving multiple medications and those with renal or liver disorders are at significant risk for alterations in fluid and electrolyte status (Box 39-14). Once patients return to a restorative care setting, whether in their home or in a residential care home, drug safety becomes very important. Patient and family education is essential to providing information regarding potential drug interactions and what side effects they cause. Review all medications with patients and encourage them to consult with their local pharmacist, especially if they try a new over-the-counter medication.

❖Evaluation

Patient Care

The evaluation of a patient's clinical status is especially important if an acute fluid and electrolyte or acid-base disturbance exists. The patient's condition can change very quickly, and you must be able to recognize the signs and symptoms of

safety alert

If a blood reaction is suspected, stop the transfusion immediately.

- Keep the intravenous line open by “piggybacking” 0.9% normal saline directly into the intravenous line and running the saline.

► TABLE 39-11 Acute Transfusion Reactions

Reaction	Cause	Clinical Manifestations	Management	Prevention
Acute hemolytic	Infusion of ABO-incompatible whole blood, RBCs, or components containing 10 mL or more of RBCs Antibodies in the recipient's plasma attach to antigens on transfused RBCs, causing RBC destruction	Chills, fever, low back pain, flushing, tachycardia, tachypnea, hypotension, vascular collapse, hemoglobinuria, hemoglobinemia, bleeding, acute renal failure, shock, cardiac arrest, death	Stop transfusion. Treat shock, if present. Draw blood samples for serological testing slowly to avoid hemolysis from the procedure. Send urine specimen to the laboratory. Maintain BP with intravenous colloid solutions. Give diuretics as prescribed to maintain urine flow. Insert in-dwelling catheter or measure voided amounts to monitor hourly urine output. Dialysis may be required if renal failure occurs. Do not transfuse additional RBC-containing components until transfusion service has provided newly cross-matched units.	Meticulously verify and document patient identification from sample collection to component infusion.
Febrile, nonhemolytic (most common)	Sensitization to donor white blood cells, platelets, or plasma proteins	Sudden chills and fever (rise in temperature of greater than 1°C), headache, flushing, anxiety, muscle pain	Give antipyretics as prescribed—avoid aspirin in patients with thrombocytopenia. <i>Urgent:</i> Do not restart transfusion.	Consider leukocyte-poor blood products (filtered, washed, or frozen).
Mild allergic	Sensitivity to foreign plasma proteins	Flushing, itching, urticaria (hives)	Give antihistamine as directed. If symptoms are mild and transient, transfusion may be restarted slowly. <i>Urgent:</i> Do not restart transfusion if fever or pulmonary symptoms develop.	Treat prophylactically with antihistamines.
Anaphylactic	Infusion of IgA proteins to IgA-deficient recipient who has developed IgA antibody	Anxiety, urticaria, wheezing, progressing to cyanosis, shock, possible cardiac arrest	Initiate CPR, if indicated. Have epinephrine ready for injection (0.4 mL of a 1:1000 solution subcutaneously or 0.1 mL of 1:1000 solution diluted to 10 mL with saline for intravenous use). <i>Urgent:</i> Do not restart transfusion.	Transfuse extensively washed RBC products, from which all plasma has been removed. Alternatively, use blood from IgA-deficient donor.
Circulatory overload	Fluid administered faster than the circulation can accommodate	Cough, dyspnea, pulmonary congestion (rales), headache, hypertension, tachycardia, distended neck veins	Place patient upright with feet in dependent position. Administer prescribed diuretics, oxygen, morphine. Phlebotomy may be indicated.	Adjust transfusion volume and flow rate on the basis of patient size and clinical status. Have transfusion service divide unit into smaller aliquots for better spacing of fluid input.
Sepsis	Transfusion of contaminated blood components	Rapid onset of chills, high fever, vomiting, diarrhea, and marked hypotension and shock	Obtain culture of patient's blood and send bag with remaining blood to transfusion service for further study. Treat septicemia as directed—antibiotics, intravenous fluids, vasopressors, steroids.	Collect, process, store, and transfuse blood products according to blood banking standards and infuse within 4 hours of starting time.

(2005). *AABB technical manual* (15th ed.). Bethesda, MD: American Association of Blood Banks; and Goodnough, L. T. (2005). Risks of blood transfusions. *Anesthesiology Clinics of North America*, 23, 241.

* BOX 39-13 PATIENT TEACHING

Home Intravenous Therapy

Objectives

- The patient, the primary caregiver, or both will demonstrate understanding and competence with intravenous therapy for safe delivery of medication in the home setting.

Teaching Strategies

- Explain to the patient and the primary caregiver the importance of intravenous therapy in maintaining hydration and access for the delivery of medications.
- Ensure that the patient and primary caregiver understand the risks involved when the intravenous system is not kept sterile.
- Be sure that the patient, the primary caregiver, or both can manipulate the required equipment.
- Instruct the patient and the primary caregiver in aseptic technique and hand hygiene when handling all intravenous equipment.
- Instruct the patient and the primary caregiver in how to change intravenous solutions, tubing, and dressings when they become soiled or dislodged. (Note: The home care nurse may be able to visit frequently enough to perform scheduled tubing and dressing changes.)
- Instruct the patient and the primary caregiver in procedures for safe disposal, in appropriate containers, of all sharps and intravenous materials exposed to blood.
- Instruct the patient and the primary caregiver about signs and symptoms of infiltration, phlebitis, and infection and about reporting symptoms immediately.
- Instruct the patient, the primary caregiver, or both to report slowing or cessation of the infusion or to report the presence of blood in the tubing.
- Teach the patient, with the primary caregiver's assistance, how to ambulate, perform hygiene, and participate in other activities of daily living without dislodging or disconnecting cannula and tubing.

Evaluation

- Ask the patient and the primary caregiver why it is necessary to maintain hydration and intravenous access for the delivery of medications.
- Ask the patient and the primary caregiver what to do if intravenous fluid stops.
- Ask the patient and the primary caregiver to describe signs and symptoms of complications and the actions they should take.
- Observe the patient, the primary caregiver, or both changing the intravenous container, tubing, and dressing.
- Observe the patient ambulating and participating in activities of daily living to see how he or she protects and manipulates the intravenous cannula and apparatus.

impending problems by being aware of health alterations, the effects of medications and fluids, and the patient's presenting clinical status (Figure 39-18).

You determine whether changes have occurred from the last patient assessment, and you assess such changes. For example, the physical signs and symptoms of the assessed condition begin to disappear or lessen in intensity.

For patients with less acute alterations, evaluation likely occurs over a longer period of time. In this situation, your evaluation may be focused more on behavioural changes (e.g.,

* BOX 39-14 RESEARCH HIGHLIGHT

Managing Chronic Kidney Disease

Research Focus

Prevention of complications associated with chronic kidney disease requires attention to many biochemical parameters. In nurse-run clinics, nurses, with the guidance of physicians, are able to successfully manage these parameters through patient-centred care, health promotion, teaching, dealing with problems, time, protocols, consultations or referrals, logistics, paperwork or documentation, and nurse-physician collaboration.

Research Abstract

The purpose of the study conducted by Molzahn et al. (2008) was to describe the nature of the care provided to people with chronic kidney disease in a larger study of nurse-run, physician-monitored clinics and to describe how patients, nurses, and nephrologists described their experience with the clinics. Seven nurses, five physicians, and 22 patients participated in interviews, which were tape-recorded and transcribed. In addition to interviews, data collection involved review of 40 randomly selected charts. Themes identified related to the characteristics of the nurse, patient-centred care, health promotion, teaching, dealing with problems, time, protocols, consultations or referrals, logistics, paperwork or documentation, and nurse-physician collaboration. Challenges and outcomes were also described as part of the experience with the clinic. Patients were actively engaged in self-management and reported high levels of satisfaction with care, as well as improvements in selected outcomes. Overall, the perceptions about this model of care were positive, and the approach warrants further exploration.

Evidence-Informed Practice and Primary Health Care

- Regular assessment and management by nurses can be used to prevent cardiovascular disease and other complications of chronic kidney disease.
- Patient-centred care, teaching, and health promotion are important processes in caring for the patient with chronic kidney disease.
- Many people with chronic kidney disease are able and willing to self-manage their illness.

References: Molzahn, A. E., Pelletier Hibbert, M., Gaudet, D., Starzomski, R., Barrett, B., & Morgan, J. (2008). Managing chronic kidney disease in a nurse-run, physician-monitored clinic: The CanPREVENT experience. *Canadian Journal of Nursing Research*, 40, 96–112.

the patient's ability to follow dietary restrictions and medication schedules). The family's ability to anticipate alterations and prevent problems from recurring is also an important element of evaluation.

The patient's level of progress determines whether you need to continue or revise the care plan. If goals are not met, you may need to consult with a physician and discuss additional methods, such as increasing the frequency of an intervention (e.g., provide more fluids to a dehydrated patient), introducing a new therapy (e.g., initiate insertion of an intravenous line), or discontinuing a particular therapy. Once outcomes have been met, you can resolve the nursing diagnosis and focus on other priorities.

Patient Expectations

You routinely review with the patient his or her success in meeting expectations of care. "Tell me if I have helped you feel more comfortable" is a request you might make if the patient's

Figure 39-18 Critical thinking model for evaluation of fluid, electrolyte, and acid-base balances. BP, Blood pressure.

expectations revolve around comfort and symptom management. If the patient's concerns involve having a better understanding of a chronic problem, your evaluation might focus on the patient's satisfaction with educational offerings. Often the patient's level of satisfaction with care also depends on your success in involving family and friends. If the patient has concerns about returning home or to a different care setting, it will be important to evaluate if the patient feels prepared for the transition from acute care.

❖ KEY CONCEPTS

- Body fluids are distributed in ECF and ICF compartments.
- Body fluids are composed of electrolytes, minerals, cells, and water.
- Body fluids are regulated through fluid intake, fluid output, and hormonal regulation.
- Volume disturbances include isotonic and osmolar deficits and excesses.
- Electrolytes are regulated by dietary intake and hormonal controls.
- Acid-base imbalances are buffered by chemical, biological, and physiological buffering, especially the lungs and kidneys.
- Chronic and serious illnesses increase the risk of fluid, electrolyte, and acid-base imbalances.

- Patients who are very young or very old are at greater risk for fluid, electrolyte, and acid-base imbalances.
- Assessment for fluid, electrolyte, and acid-base alterations includes the nursing health history, physical and behavioural assessments, measurements of intake and output, daily weights, and specific laboratory data.
- Osmolar imbalances and FVD can be corrected by enteral or parenteral administration of fluid.
- Common complications of intravenous therapy are infiltration, phlebitis, infection, FVE, and bleeding at the infusion site.
- Blood transfusions are given to replace fluid volume loss from hemorrhage, treat anemia, or replace coagulation factors.
- Blood transfusions can be obtained from a donor, autologous, or obtained through perioperative salvage.
- Administration of blood or blood products requires the nurse to follow a specific procedure to identify transfusion reactions quickly.
- In addition to transfusion reactions, the risks of transfusion also include hyperkalemia, hypocalcemia, FVE, and infection.
- Treatment for electrolyte disturbances includes dietary and pharmacological interventions.
- The body's chemical buffering system responds first to acid-base abnormalities.
- The goals of therapy for acid-base imbalances are to treat the underlying illness and to restore the arterial blood pH to normal.
- With new technology emerging continually, nurses need to stay current on evidence to inform practice, particularly in relation to VADs.

❖ CRITICAL THINKING EXERCISES

1. Mrs. Emanuele is an 81-year-old woman admitted to the hospital with a three-day history of vomiting and diarrhea. She has had only ice chips since the first episode of vomiting and is now complaining of malaise, cramping muscles, and a temperature of 39°C. Which laboratory findings would you expect to be abnormal on the basis of her complaints? What interventions would you expect the physician to order?
2. Caroline, a nurse, has just received a new patient on her unit who is to receive one unit of RBCs within the next hour. What nursing actions are necessary before administering blood? Can Caroline delegate the administration of blood to a licensed practical nurse or an unregulated care provider?
3. Carlos is caring for Mr. Rossi, a 52-year-old man who has been seen in the emergency department following a motor vehicle accident. Mr. Rossi is complaining of difficulty breathing and has a respiratory rate of 40 breaths per minute. He is transferred to the intensive care unit, intubated, and placed on a ventilator. A nursing student asks Carlos to interpret Mr. Rossi's last ABG results: pH = 7.30; PaO₂ = 70; PaCO₂ = 50; bicarbonate = 24 mmol/L. What interpretation will Carlos give to the student nurse? What is the relationship between the ABG results and Mr. Rossi being intubated and ventilated?
4. Janelle is the nurse caring for Mrs. Kwan, a 59-year-old woman who has just had a total knee replacement. The physician has ordered cefazolin (Ancef) 1 g in 50 mL to run over 30 minutes intravenous piggyback three times daily. Mrs. Kwan has a continuous infusion of Ringer's lactate at 75 mL/hour in the left forearm. What type of tubing will Janelle use to administer the intravenous piggyback medication? Calculate the drops per minute of the piggyback using both microtubing (60 drops/mL) and macrotubing (15 drops/mL).

5. Mrs. Yoe is on a surgical unit following a total abdominal hysterectomy. She experienced postoperative bleeding and requires blood products; however, because of religious and cultural reasons, she has refused blood products. What are the key principles in providing care for Mrs. Yoe? How does a health promotion perspective inform your care? What other options are available, and how realistic or viable are these options?
6. A 24-year-old tennis professional was admitted to the clinic with a temperature of 41°C. He has a history of playing in a five-hour tennis match in 38°C heat. His coach brought him to the clinic because he was weak and lethargic. What assessment findings would you expect to find? What interventions would be necessary? Describe a teaching plan for this patient upon discharge.

✦ REVIEW QUESTIONS

1. One of the most common electrolyte imbalances is
 1. Hypokalemia
 2. Hyperkalemia
 3. Hyponatremia
 4. Hypocalcemia
2. The patient most at risk for FVDs is a(n)
 1. Older adult
 2. Young to middle adult
 3. Child
 4. Infant
3. One reason that older adults experience fluid and electrolyte imbalance and acid-base imbalances is that they
 1. Eat poor-quality food
 2. Have a decreased thirst sensation
 3. Have a more severe stress response
 4. Have an overly active thirst response
4. Output recorded on an intake and output record includes
 1. Urine, vomitus, diarrhea, and drainage from wounds
 2. Diarrhea, gastric suction, and drainage from wounds
 3. Medications, juices, and water
 4. Urine, diarrhea, vomitus, gastric suction, and drainage from wounds or tubes
5. Health promotion activities in the area of fluid and electrolyte imbalances focus primarily on
 1. Patient teaching
 2. Dietary intake
 3. Medication regimen
 4. Physician involvement in care
6. The nurse is aware that the following medication is never given directly intravenously:
 1. Potassium chloride (KCl)
 2. Furosemide (Lasix)
 3. Dextrose
 4. Calcium gluconate
7. Many factors are initially controlled for in the intravenous insertion procedure. The nurse understands that this begins with
 1. Hand hygiene
 2. Checking the sterility of supplies
 3. Ensuring the seven rights of medication administration
 4. Carefully checking the order for the intravenous therapy

8. Indications of intravenous fluid infiltration include
 1. Phlebitis and coolness
 2. Edema and erythema
 3. Pallor and coolness
 4. Pain and erythema
9. Recent evidence-informed review recommends that replacing peripheral venous catheters and rotating sites should occur
 1. Every 96 hours
 2. Every 72 hours
 3. When clinically indicated
 4. Every 48 hours
10. Fifteen minutes following blood administration, your patient develops dyspnea, a cough, and a rapid heart rate. You suspect
 1. Sepsis
 2. Anaphylaxis
 3. Acute hemolytic reaction
 4. Circulatory overload

✦ RECOMMENDED WEB SITES

Association for Vascular Access: <http://www.avainfo.org>

This Web site for the Association for Vascular Access has many links to conferences and national and international organizations in relation to venous access.

Canadian Association of Nephrology Nurses and Technologists: <http://www.cannnt.ca>

This association exists to promote excellence in the care of patients with renal disease. They provide leadership through education, research, and dissemination of research. Nephrology Nursing Standards are available from the Web site and include standards for holistic patient care across areas of practice, such as prevention, assessment, and nursing interventions.

Canadian Vascular Access Association: <http://www.cvaa.info/>
The Canadian Vascular Access Association provides leadership in advocating for safe, quality vascular access by promoting education, partnerships, knowledge, and research. The mission statement states the CVAA is "dedicated to the promotion and achievement of excellence in vascular access in Canada."

MedCalc: Acid-Base Calculator: <http://www.medcalc.com/acidbase.html>

The MedCalc acid-base program provides a calculator for acid-base status and anion gap. Other options are calculators for creatinine clearance, fractional excretion of sodium, free water deficit, and hypo- and hypernatremia.

Registered Nurses' Association of Ontario (RNAO) Nursing Best Practice Guidelines: <http://www.rnao.org> and click on Nursing Best Practice Guidelines or go to <http://www.rnao.org/Page.asp?PageID=861&SiteNodeID=133>

The Registered Nurses' Association of Ontario has developed Best Practice Guidelines for a number of aspects of nursing care, including intravenous therapy. These guidelines are based on current evidence and knowledge and constitute an excellent resource.

Sleep

Original chapter by Patricia A. Stockert, RN, BSN, MS, PhD

Canadian content written by Claudette Taylor, RN, MN

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Define sleep.
- Compare the characteristics of rest and sleep.
- Explain the effect of the 24-hour sleep–wake cycle on biological functions.
- Discuss the mechanisms that regulate sleep.
- Describe the stages of a normal sleep cycle.
- Explain the functions of sleep and rest.
- Compare the sleep requirements of different age groups.
- Identify factors that normally promote sleep and factors that normally disrupt sleep.
- Discuss the characteristics of common sleep disorders.
- Conduct a sleep history for a patient.
- Identify nursing diagnoses appropriate for patients with sleep alterations.
- Identify nursing interventions designed to promote normal sleep cycles for patients of all ages.
- Describe ways to evaluate sleep therapies.

Sleep is necessary for health. Sleep is a basic necessity of life and is as important as air, food, and water (National Sleep Foundation, 2009a). Everyone requires sleep. For a variety of reasons, individuals are, on average, sleeping less. Continual sleep loss may have many, yet largely unknown, outcomes for health and well-being. In the short term, insufficient sleep alters mood and decreases the ability to concentrate, make decisions, and participate in daily activities.

To help patients by identifying and treating their sleep pattern disturbances, you need to first understand the nature of sleep, the factors influencing sleep, and patients' sleep habits. Patients require an individualized approach that is determined on the basis of their personal habits and patterns of sleep and addresses the particular problem that is disrupting their sleep. Nursing interventions are often effective in resolving short- and long-term sleep disturbances.

Sleep provides healing and restoration (Van Cauter et al., 2008). Achieving the best possible sleep quality contributes to good health and to recovery from illness. Ill

patients often require more sleep and rest than healthy patients. The nature of illness, however, often prevents some patients from getting adequate rest and sleep. Sleep can also be made difficult by the environment of a hospital or long-term care facility and the activities of health care providers. Some patients have preexisting sleep disturbances, whereas other patients develop sleep problems as a result of illness or hospitalization.

Scientific Knowledge Base

Definition of Sleep

Sleep is a universal, dynamic, highly organized, physiological, and behavioural state required by most living organisms to maintain health and well-being (see Box 40-1) (Carskadon & Dement, 2011; Collop et al., 2008).

Physiology of Sleep

Sleep is a cyclical physiological and behavioural process that alternates with longer periods of wakefulness. Sleep physiology is controlled by three distinct processes: an *ultradian* process, a *homeostatic* process (process S), and a *circadian* process (process C). The ultradian process occurs within the sleep state and is characterized by the alteration of the two sleep stages: nonrapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. Process S and process C work together to regulate the timing and organization of sleep and wakefulness. Process S is dependent on the sleep–wake cycle, whereas process C functions to maintain a state of wakefulness (Achermann & Borbély, 2011; Lee-Chiong, Jr., 2008).

Circadian Rhythms. The biological functions of most living organisms are regulated by **circadian rhythms**. The term *circadian* is derived from the Latin words *circa*, which means “about,” and *dien*, which means a day (Smith et al., 2008). People experience cyclical rhythms as part of their everyday life. The sleep–wake cycle is the most familiar of the 24-hour circadian rhythms. Numerous biological and behavioural functions are influenced by circadian rhythms. Changes in body temperature, for example, exhibit circadian rhythmicity. Normally, a person’s body temperature peaks in the afternoon, decreases gradually, and then drops sharply after a person falls asleep. The initial period of a person’s sleep is characterized by high levels of growth hormones and increased blood glucose concentrations, blood pressure, and heart rate. Sensory acuity and mood are also maintained by the 24-hour circadian cycle (Laposky et al., 2008).

Factors that affect circadian rhythms and daily sleep–wake cycles include light, temperature, social activities, and work

routines. All individuals have **biological clocks** that synchronize their sleep–wake cycles, which explains why some individuals fall asleep at 9 P.M., whereas others go to bed at midnight. Different individuals also function at their best at different times of the day.

Hospitals or extended care facilities usually do not adapt care to an individual’s sleep–wake cycle preferences. Typical hospital routines often interrupt sleep or prevent patients from falling asleep at their usual time. A person has poor quality of sleep if his or her sleep–wake cycle changes significantly. A serious illness is often indicated by reversals in the sleep–wake cycle, such as falling asleep during the day (or vice versa for people who work nights).

When the sleep–wake cycle is disrupted (e.g., by working rotating shifts), other physiological functions can also change. For example, the person may experience a decreased appetite and lose weight or may experience other common symptoms of sleep cycle disturbances, such as anxiety, restlessness, irritability, and impaired judgement. Failure to maintain the usual sleep–wake cycle can negatively influence the patient’s overall health.

Sleep Regulation. Sleep involves a sequence of physiological and behavioural states maintained by highly integrated central nervous system (CNS) activity, which is associated with changes in the autonomic nervous system and endocrine, cardiovascular, respiratory, gastrointestinal, renal, and musculoskeletal systems (Lee-Chiong, Jr., 2008). Each sequence of physiological states is identified by specific physiological responses and patterns of brain activity. Special instruments provide information about the structural and physiological aspects of sleep: for example, the electroencephalogram (EEG) measures electrical activity in the cerebral cortex, the electromyogram (EMG) measures muscle tone, and the electrooculogram (EOG) measures eye movements.

Current theory suggests that sleep is a dynamic multiphase process. The body’s major sleep centre is the hypothalamus. The hypothalamus secretes hypocretins (orexins) that promote wakefulness and sleep. The anterior pituitary gland also secretes hormones (e.g., growth hormone and prolactin) that promote sleep (Lee-Chiong, Jr., 2008).

Researchers believe the ascending reticular activating system (RAS), located in the upper brain stem, contains special cells that maintain alertness and wakefulness. The RAS receives visual, auditory, pain, and tactile sensory stimuli. Activity from the cerebral cortex (e.g., emotions and thought processes) also stimulates the RAS. Arousal, wakefulness, and maintenance of consciousness result from neurons in the RAS that release serotonin and catecholamines, such as norepinephrine and dopamine (Siegel, 2011).

Whether a person remains awake or falls asleep depends on a balance of impulses received from higher centres (e.g., thoughts), peripheral sensory receptors (e.g., sound or light stimuli), and the limbic system (e.g., emotions) (Figure 40-1). As a person tries to fall asleep, the eyes close and the body assumes a relaxed position. Stimuli to the RAS decline. If the room is dark and quiet, activation of the RAS further declines. At some point, an area of the brain called the bulbar synchronizing region (BSR) takes over, causing sleep.

Stages of Sleep. Changes in brainwave activity, muscle tone, body temperature, and eye movements are associated with different stages of sleep (Billard, 2008). Within sleep, two separate phases have been identified: **nonrapid eye movement (NREM) sleep** and **rapid eye movement (REM) sleep** (see Box

► BOX 40-1

Behavioural Characteristics of Sleep

- Periodic
- Involuntary
- Reversibility
- Reduced responsiveness to environment
- Minimal movement
- Closed eyes
- Species-specific posture

Source: Carskadon, M. A., & Dement, W. C. (2011). Normal human sleep: An overview. In M. H. Kryger, T. Roth, & W. C. Dement (Eds.), *Principles and practice of sleep medicine* (5th ed., pp. 16–41). Philadelphia, PA: Elsevier.

Figure 40-1 The reticular activating system and the bulbar synchronizing region control sensory input by intermittently activating and suppressing the brain's higher centres to control sleep and wakefulness.

40-2). During NREM sleep, a sleeper progresses through four stages (stages 1, 2, 3, and 4) of increasingly deeper sleep. Stage 1, a light and drowsy sleep, occurs at the beginning of sleep and is the transitional stage between wakefulness and sleeping. Stage 2 is a deeper stage of sleep; however, a sleeper may be easily aroused during this stage of sleep. Stages 3 and 4 involve a deeper sleep, and these stages are referred to as delta sleep or slow-wave sleep (SWS). Delta sleep or SWS sleep are thought to be the most restorative of all the sleep stages. Most recently, the American Academy of Sleep Medicine has revised the classification of NREM sleep into three NREM stages (Stages 1, 2, and 3, with 3 representing the traditional stages of 3 and 4). REM sleep, also known as paradoxical sleep, follows NREM sleep and is not divided into stages. REM sleep shares some characteristics of NREM sleep and of wakefulness. REM sleep is "paradoxical" in the sense that, although a person is behaviourally asleep, the individual is physiologically active—brain activity is high, rapid eye movements are occurring, twitches of the extremities occur, and males frequently develop erections (Siegel, 2011). The most characteristic feature of REM sleep is dreaming. REM sleep dreams are often vivid and emotional (Billard, 2008; Van Cauter et al., 2008). REM sleep is the phase at the end of each sleep cycle.

Different factors promote or interfere with various stages of the sleep cycle. It is important to choose therapies that promote sleep and eliminate factors that disrupt it.

Sleep Cycle. The normal sleep pattern for an adult begins with a presleep period during which the person is aware of only gradually developing sleepiness. This period normally lasts 10 to 30 minutes, but if a person has difficulty falling asleep, it can last an hour or longer. Once asleep, the person usually passes through four to five complete sleep cycles per night, each consisting of four stages of NREM sleep and a period of REM sleep (Billard, 2008). Sleep begins when adults enter stage 1 NREM sleep. This stage usually persists for only a few minutes, and sleep may be easily interrupted by calling the person's name or by touching them. Stage 2 NREM sleep follows and continues for approximately 10 to 25 minutes. In

► BOX 40-2 Stages of the Sleep Cycle

Stage 1: Nonrapid Eye Movement

This stage represents the lightest level of sleep.

Person is unresponsive but easily aroused by sensory stimuli, such as noise.

Physiological activity begins to decrease, accompanied by a gradual fall in vital signs and metabolism.

Muscle tone is present.

When awakened from this stage, a person feels as though he or she had been daydreaming.

This stage lasts only a few minutes.

Accounts for about 2% to 5% of total sleep time in adults.

Stage 2: Nonrapid Eye Movement

This stage is a period of sound sleep.

Relaxation progresses.

Body functions continue to slow.

Muscle tone remains present.

Eye movements are absent.

Accounts for the greatest proportion (45% to 55%) of total sleep time in adults.

Stage 3: Nonrapid Eye Movement

This stage begins the initial period of deep sleep.

Individuals are difficult to arouse.

Muscles become completely relaxed.

Vital signs decline but remain regular.

Parasomnias sometimes occur during this stage (e.g., sleepwalking, enuresis [bedwetting]).

Accounts for 10% of total sleep time in adults and is more prominent during the first half of sleep.

Stage 4: Nonrapid Eye Movement

This stage is the deepest period of sleep.

Individuals are difficult to arouse.

If sleep loss has occurred previously, the sleeper will spend a considerable portion of the sleep period in this stage.

The vital signs are significantly lower than during waking hours.

Parasomnias sometimes occur during this stage (e.g., sleepwalking and enuresis [bedwetting]).

Accounts for 10% of total sleep time in adults and is more prominent during the first half of sleep.

Rapid Eye Movement Sleep

Rapid eye movements are present.

Respirations are irregular and shallow.

Variable heart rate and blood pressure.

Vivid and elaborate dreams sometimes occur.

Dreaming occurs more frequently and is more complex compared with NREM sleep.

This stage usually begins about 90 minutes after sleep has begun.

Loss of skeletal muscle tone occurs.

Gastric secretions increase.

The person is difficult to arouse.

The duration of REM sleep increases with each cycle.

Accounts for about 25% of total sleep time in adults.

Figure 40-2 The stages of the adult sleep cycle.

stage 2, a person is not so easily awakened. Stages 3 and 4 NREM sleep and REM sleep follow and complete the sleep cycle (Figure 40-2). NREM sleep and REM sleep continue to alternate throughout a night in this cyclical pattern (Carskadon & Dement, 2011; Lee-Chiong, Jr., 2008). The number of sleep cycles depends on the total amount of time that a person spends sleeping.

The average length of the first cycle is 90 minutes, and subsequent cycles may last between 100 and 120 minutes. During the night, the NREM/REM sleep cycle is repeated three to six times, and with each cycle less time is spent in Stage 3 and 4 NREM sleep while the proportion of time spent in REM sleep increases. Of the total sleep time, 75% to 85% is spent in NREM sleep.

Not all people progress consistently through the stages of sleep. For example, a sleeper may move back and forth for short intervals between the NREM stages 2, 3, and 4 before entering the REM stage. The amount of time spent in each stage varies over a person's lifespan. Newborns and children spend more time in deep sleep or slow-wave sleep (SWS). SWS is highest in children, and for this reason it is very difficult to wake young children from this stage of sleep. As individuals age, sleep becomes more fragmented and less time is spent in deep sleep (Carskadon & Dement, 2011; Lee-Chiong, Jr., 2008).

Functions of Sleep

Although we spend a third of our time sleeping, many of the reasons why we sleep have yet to be discovered and understood. Many functions have been proposed, and all of these may be partially correct. It has been proposed that sleep allows for physiological and psychological restoration (Van Cauter et al., 2008). During NREM sleep, biological functions slow. Normally, in daytime hours the heart rate of a healthy adult averages 70 to 80 beats per minute, or less if the individual is in excellent physical condition. During sleep, the heart rate slows, beating 10 to 26 fewer times each minute or 60 to 120 fewer beats each hour. Clearly, restful sleep is beneficial in preserving cardiac function. Other biological functions also decrease during sleep; for example, respirations, blood pressure, muscle tone, urine production, and hormone secretion (Carskadon & Dement, 2011).

The body needs sleep for physiological restoration such as cell and tissue repair. Increased cell mitosis and increased protein synthesis have been observed during periods of NREM sleep (Van Cauter et al., 2008).

REM sleep is necessary for brain tissue restoration and appears to be important for cognitive restoration (Lee-Chiong, Jr., 2008). REM sleep is associated with changes in cerebral

blood flow, increased cortical activity, increased oxygen consumption, and epinephrine release (Carskadon & Dement, 2011). During sleep, the brain filters stored information about the day's activities. The benefits of sleep on behaviour often go unnoticed until a problem develops as a result of sleep deprivation. A loss of REM sleep leads to feelings of confusion and suspicion.

Sleep is also believed to be important for immune function, renal function, regulation of body temperature, metabolism of glucose, and hormone secretion (Collop et al., 2008; Tibbitts, 2008).

In addition to physical functioning, sleep is essential for psychological and social functioning. Without sleep, individuals are irritable and anxious and often report high levels of stress.

Dreams. Dreaming is defined as a mental activity that occurs while individuals are asleep. Dreams can occur during both NREM and REM sleep. The majority of dreams take place in the REM sleep stage. REM sleep-related dreams are often vivid and elaborate, whereas NREM dreams are simpler and more realistic (Lee-Chiong, Jr., 2008; Nielsen, 2011).

Studies of across-the-night changes in the characteristics of dreams suggest that dreams become more realistic as the night progresses. Dream content also appears to parallel cognitive and emotional development, as the recollection of dreams reported by children and adults is quite different (Stickgold & Wamsley, 2011).

Determinants of dreams, aside from age, include personality, physiological conditions (e.g., pregnancy), psychological conditions, pharmacological therapies, and situational factors. Personality also influences the quality of dreams; for example, a creative person has elaborate and complex dreams, whereas a depressed person dreams of helplessness (Stickgold & Wamsley, 2011). Most people dream about their immediate concerns, such as an argument with a spouse or worries over work. Sometimes a person is unaware of the fears represented in bizarre dreams. Clinical psychologists can try to analyze the symbolic nature of dreams as part of a patient's psychotherapy. The ability to describe a dream and interpret its significance sometimes helps resolve personal concerns or fears.

Numerous theories have been proposed as to why individuals dream. For centuries, dreams have been seen as messages from the gods, and this belief is upheld by many cultures today. Sigmund Freud theorized that dreams were the expression of an individual's unconscious desires and that by exploring dreams, emotional problems could be cured (Stickgold & Wamsley, 2011).

Physical Illness

Any illness that causes pain, physical discomfort, or mood problems, such as anxiety or depression, often results in sleep problems. Individuals who are ill frequently have trouble falling asleep or staying asleep. Illnesses can also force patients to sleep in unfamiliar positions. For example, when an arm or leg is in traction, patients have a difficult time finding a comfortable position for sleep.

Respiratory disease often interferes with sleep. While individuals sleep, their level of blood oxygen decreases. In healthy individuals, this decrease can be compensated easily while individuals with respiratory diseases often require supportive devices, practices, or therapies to assist them while they are sleeping (Agarwal et al., 2009). Symptoms associated with respiratory diseases may require individuals to alter their

position to facilitate sleeping. For example, individuals with chronic obstructive lung disease, such as emphysema, are frequently short of breath and often require two or three pillows to sleep (Lee-Chiong, Jr., 2008).

Cardiovascular diseases interfere with sleep (Box 40-3). Chest pain, shortness of breath, diaphoresis, nausea, and palpitations, all symptoms associated with cardiovascular disease, frequently occur during the night and disrupt sleep. Hypertension often causes early morning awakening and fatigue (Lee-Chiong, Jr., 2008).

The sleep of individuals with musculoskeletal disorders such as osteoarthritis and rheumatoid arthritis may be disrupted by the pain that often accompanies these conditions (Lavigne et al., 2011).

BOX 40-3 RESEARCH HIGHLIGHT

Sleep Duration and Obesity

Research Focus

Research has shown an association between obesity, sleep time, and the occurrence of sleep disorders. The prevalence of obesity has increased considerably over the past 25 years and is currently considered a global epidemic (Magee et al., 2008). Obesity refers to an excess of body fat and is a disorder that occurs when body fat excess impairs the health of individuals. Obesity is associated with an increased risk of many chronic diseases, including heart disease, diabetes, hypertension, and cancer (Anic et al., 2010). Prior research has shown obesity increases morbidity and mortality.

Shorter sleep time have become increasingly more prevalent in Western countries because of many reasons, including lifestyle choices, work or family requirements, or existing physical or psychological problems. Over the past several years, sleep duration in adults has decreased, on average, by 1.5 to 2 hours per night, and many individuals are reporting sleeping less than 6 hours per night. Researchers wanted to determine whether shorter sleep time increases the risk of obesity.

Research Abstract

Researchers (Patel, Blackwell, et al., 2008) assessed the sleep pattern of 3,110 older men and 3,219 older women using wrist actigraphy, an objective method of sleep assessment. Study results demonstrated that a sleep duration of less than five hours was associated with an increased body mass index and truncal (abdominal) fat, the fat also associated with cardiovascular disease and diabetes.

Evidence-Informed Practice

- During your assessment of a patient's health problems, ensure that you ask questions related to sleep quality and sleep patterns.
- If the patient indicates a problem with sleep, conduct a thorough sleep history.
- Reinforce good sleep hygiene habits.
- Encourage patients to notify their health care provider if they begin to experience sleep problems.
- Reinforce healthy eating habits.
- Encourage patients to seek the advice of other health care providers (e.g., dietitian, nutritionist).

Reference: Patel, S. R., Blackwell, T., Redline, S., Ancoli-Israel, S., Cauley, J. A., Hillier, T. A., ... & Stone, K. L. (2008). The association between sleep duration and obesity in older adults. *International Journal of Obesity*, 32(12), 1825-1834.

Nocturia, or urination during the night, disrupts sleep and the sleep cycle. This condition is most common in older people with reduced bladder tone or individuals who have cardiac disease, diabetes, or problems with elimination. After a person awakens repeatedly to urinate, returning to sleep is difficult.

Sleep Disorders

Sleep disorders are conditions that interfere with nighttime sleep. Currently, more than 80 sleep disorders have been identified in the literature. The American Academy of Sleep Medicine developed the International Classification of Sleep Disorders version 2 (ICSD2), which classifies these disorders into eight major categories (Box 40-4).

Increasingly, evidence suggests sleep disorders are related to serious medical conditions. Individuals with sleep disorders are at risk for developing hypertension, diabetes, and cardiovascular and neurological diseases. Sleep disorders can affect individuals of all ages, and the prevalence of these disorders increases with advancing age (Bloom et al., 2009). Individuals with sleep disorders may complain of difficulty falling asleep or staying asleep, daytime sleepiness, **hypersomnolence** or abruptly falling asleep during the daytime (Bae & Avidan, 2008).

The insomnias are primary disorders related to difficulty falling asleep. Individuals with sleep-related breathing disorders have disordered respirations during sleep. Hypersomnia not due to sleep-related breathing disorders is a group of disorders that are not caused by disturbances in circadian rhythms or in nocturnal sleep. The **parasomnias** are undesirable behaviours that usually occur during sleep. Sleep disturbances and wake disturbances are associated with many medical and psychiatric sleep disorders, including psychiatric, neurological, and other medical disorders. The circadian rhythm sleep disorders are caused by a misalignment between the timing of sleep and the societal norm or the desires of the individual. In sleep-related movement disorders, the person experiences movements such as leg cramps or teeth grinding that disturb sleep. The "other sleep disorders category" contains sleep problems that do not fit into other categories.

Sleep laboratory studies are often used to diagnose a sleep disorder (Chervin, 2011). A **polysomnogram** involves the use of EEG, EMG, and EOG to monitor stages of sleep and wakefulness during nighttime sleep. The Multiple Sleep Latency Test (MSLT) provides objective information about sleepiness and selected aspects of sleep structure by measuring eye movements, muscle tone changes, and brain electrical activity during at least four napping opportunities spread throughout the day. The MSLT takes 8 to 10 hours to complete. Patients wear an Actigraph device on the wrist to measure sleep-wake patterns over an extended period of time. Actigraphy data provide information such as sleep time, number and duration of awakenings, and levels of activity and rest (Chervin, 2011).

Insomnia. Patients experience **insomnia** when they report problems falling asleep, staying asleep, or nonrestorative sleep. Insomnia is the second most commonly expressed complaint reported in clinical practice after pain and the most common self-reported sleep-related complaint (Wyatt & Crisostomo, 2008). Insomnia is more common in women and its incidence increases with advancing age (Doghranji, 2010). Insomnia may be transient and may indicate an underlying physical or psychological disorder (Reeve & Bailes, 2010). People experience *transient insomnia* as a result of schedule

► BOX 40-4 Classification of Sleep Disorders

Insomnias

Acute insomnia (duration of less than one month)
 Primary insomnia (unrelated to any other disorder)
 Co-morbid insomnia (due to a medical condition)
 Nonrestorative sleep
 Early morning awakening

Sleep-Related Breathing Disorders

Sleep apnea

Obstructive sleep apnea syndrome
 Central sleep apnea syndromes
 Primary central sleep apnea
 Central sleep apnea due to a drug or substance
 Central sleep apnea due to a medical condition

Snoring

Upper airway resistance syndrome

Excessive Sleepiness

Narcolepsy
 Narcolepsy secondary to medical disorders
Hypersomnias
 Idiopathic hypersomnia (no identifiable cause)
 Recurrent hypersomnia (repeated episodes of hypersomnia)
 Post-traumatic hypersomnia (associated with head injuries)
 Menstrual-related hypersomnia
 Behaviourally induced Insufficient Sleep Syndrome

Parasomnias

Disorders of Arousal

Sleepwalking
 Sleep terrors

Parasomnias Usually Associated With REM Sleep

Nightmare disorder
 REM sleep behaviour disorder
 Sleep paralysis

Other Parasomnias

Sleep-related groaning
 Sleep-related hallucinations
 Sleep-related eating disorder
 Sleep-related enuresis (bedwetting)
 Due to drug or substance
 Due to a medical condition

Circadian Rhythm Sleep Disorders

Primary Circadian Rhythm Sleep Disorders

Delayed sleep phase type
 Advanced sleep phase type

Behaviourally Induced Circadian Rhythm Sleep Disorders

Jet lag type
 Shift work type
 Delayed sleep phase type
 Drug or substance use

Sleep-Related Movement Disorders

Restless leg syndrome
 Periodic limb movements
 Sleep-related leg cramps
 Sleep-related bruxism (teeth grinding)

Isolated Symptoms, Apparently Normal Variants, and Unresolved Issues

Long sleeper
 Short sleeper
 Snoring
 Sleep talking
 Benign sleep myoclonus of infancy

Other Sleep Disorders

Physiological (organic) sleep disorders
 Environmental sleep disorder
 Sleep disorder not due to a substance or physiological condition

Adapted from American Academy of Sleep Medicine: International classes of diseases and international classification of sleep disorders, as cited in Thorpy, M. (2011). Classification of sleep disorders. In M. Kryger, T. Roth, & W. C. Dement (Eds.), *Principles and practice of sleep medicine* (5th ed., pp. 680, 693). Philadelphia, PA: Elsevier.

changes (shift work, travel), situational crises, particular medications, and excessive intake of alcohol or caffeine. However, transient insomnia may lead to chronic difficulty in obtaining sufficient sleep if causes are not addressed (Reeve & Bailes, 2010).

Insomnia is often associated with poor **sleep hygiene**, behaviours that are problematic for initiating sleep and maintaining sleep. Management of insomnia depends on whether it is transient or indicative of an underlying disorder. Treatment may include nonpharmacological therapies such as relaxation therapy, cognitive-behavioural therapy, or pharmacological agents (e.g., hypnotics).

Behavioural and cognitive therapies have few adverse effects and show evidence of sustained improvement in sleep over a six-month period (Doghranji, 2010; Snowden, 2008).

Sleep Apnea. Sleep apnea is a disorder in which people stop breathing for a period of at least 10 seconds while asleep (Ramar & Guilleminault, 2008). There are two types of sleep apnea: obstructive sleep apnea (OSA) and central sleep apnea. Obstructive sleep apnea is the most common form of sleep

apnea and results from an obstruction of the upper airway (Cao et al., 2011). Central sleep apnea represents a loss of inspiratory effort due to an underlying pathological condition (Ramar & Guilleminault, 2008).

Risk factors for developing OSA include age, obesity, gender, ethnicity, smoking, alcohol, and a positive family history. OSA is more common in Asians than in Caucasians. OSA may affect middle-aged men more frequently, particularly when they are obese. Obstructive sleep apnea is also common in postmenopausal women and in younger women and children (Ramar & Guilleminault, 2008).

Excessive daytime sleepiness (EDS) and fatigue are the most common complaints of individuals who have OSA. Those who have severe OSA often report taking daytime naps and experience a disruption in their daily activities because of sleepiness. Feelings of sleepiness are usually most intense when waking up just after falling asleep and approximately 12 hours after the midsleep period.

In addition to reports of excessive daytime sleepiness, other symptoms of OSA are fatigue, morning headaches, choking or

gasping upon awakening, irritability, depression, difficulty concentrating, and decreased sex drive (Cao et al., 2011; Ramar & Guilleminault, 2008). Snoring is a distinguishing characteristic of OSA, as nearly all patients with this disorder snore (Cao et al., 2011).

OSA occurs when the muscles or structures of the oral cavity or throat relax during sleep. The upper airway becomes partially or completely blocked, thereby diminishing the nasal airflow (hypopnea) or stopping it (apnea) for as long as 10 to 30 seconds (Cao et al., 2011). The person still attempts to breathe; chest and abdominal movements continue and often result in loud snoring and snorting sounds. When breathing is partially or completely diminished, each successive diaphragmatic movement becomes stronger until the obstruction is relieved. Apneic episodes are normally terminated by gasps, snorting, or brief periods of awakening.

Structural abnormalities such as a deviated septum, nasal polyps, certain jaw configurations, or enlarged tonsils predispose a patient to obstructive sleep apnea. The effort to breathe during sleep results in arousals from deep sleep often to the stage 2 cycle. In severe cases, hundreds of hypopnea or apnea episodes occur every hour, resulting in severe interference with deep sleep.

Obstructive sleep apnea causes a serious decline in the saturation level of arterial oxygen. Patients with OSA are at risk for cardiac dysrhythmias, heart failure, pulmonary hypertension, angina, stroke, hypertension, and metabolic syndrome. Sleep apnea contributes to high blood pressure and increased risk for heart attack and stroke (National Sleep Foundation, 2009a).

Patients who have OSA rarely achieve deep sleep because sleep is often fragmented. OSA may exact a heavy emotional toll on the individuals affected and their families. OSA may affect marital relationships and interactions within and outside the family, and frequently is an embarrassment to the patient (National Sleep Foundation, 2009a). Treatment for OSA includes continuous positive airway pressure (CPAP). CPAP consists of a mask that fits over the nose and mouth through which air is continuously delivered into the airway to assist in keeping it open during sleep (Ramir & Guilleminault, 2008). Other treatments include addressing the underlying cardiac or respiratory complications and emotional problems that occur as a result of the symptoms of this disorder (Atwood, Jr., et al., 2011).

Narcolepsy. Narcolepsy is a common complex neurological sleep disorder for which there is no known cure. Narcolepsy is known to affect men and women of any age; however, it usually appears in adolescence. The clinical manifestations of narcolepsy are highly variable. Excessive daytime sleepiness is the most common complaint associated with narcolepsy. During the day, a person who has narcolepsy may suddenly feel an overwhelming wave of sleepiness and fall asleep (Ahmed & Thorpy, 2010). Narcolepsy is known to have a significant impact on REM sleep and is also known to intensify the emotions associated with this stage of sleep. Many individuals with narcolepsy experience hallucinations, vivid dreams, night terrors, sleepwalking, sleep paralysis, and poor memory and concentration, or the feeling of being unable to move or talk just before waking or falling asleep. **Cataplexy**, or sudden bilateral (occasionally unilateral) loss of muscle tone accompanied by an overpowering urge to sleep, can occur at any time during the day and can last from a few seconds to as long as 30 minutes. These episodes are sporadic and can occur

occasionally to several times per day. A history of cataplexy may be obtained by inquiring whether the loss of muscle tone occurs during the following: upon hearing or telling a joke, while laughing, or when angry. Other triggers are embarrassment, surprise, stress, or sexual arousal (Ahmed & Thorpy, 2010; Cook, 2008a, 2008b). Some studies show a genetic link for narcolepsy (Faraco & Mignot, 2011).

Narcolepsy may also affect energy levels, metabolism, appetite, and feelings of mental well-being. Individuals with narcolepsy can have intense cravings for carbohydrates; greater than one-third of individuals with narcolepsy suffer from obesity (Smith et al., 2008).

Most people with narcolepsy tend to be diagnosed several years after the onset of the condition, which means most of the symptoms associated with this disorder go untreated. Prior to diagnosis, individuals are frequently regarded as “different,” antisocial, lacking in motivation, and uncooperative (Jennum et al., 2009).

There is no known cure for narcolepsy, and therefore treatment is targeted at symptom management. Traditionally, individuals with narcolepsy have been treated by two groups of drugs: stimulants and antidepressants. Stimulants promote wakefulness and reduce the frequency of sleeping episodes. Modafinil is a wakefulness-promoting agent and has been shown to improve symptoms of fatigue and improve cognitive function (memory and concentration).

Antidepressants suppress cataplexy and other REM-related symptoms (Ahmed & Thorpy, 2010; Cook, 2008a, 2008b). Nonpharmacological management should be initiated in all individuals. Education is an important component of the treatment plan for individuals with narcolepsy. Good sleep hygiene should be emphasized. The fundamental principles of sleep hygiene are listed in Box 40-5. Other management strategies are to follow a regular exercise program, take strategically timed daytime naps (if possible), eat light meals that are high in protein, practice deep breathing, chew gum, and take vitamins (Cook, 2008b). Patients who have narcolepsy need to avoid factors that increase drowsiness (e.g., alcohol, heavy meals, exhausting activities, long-distance driving, and extended periods of sitting in hot, stuffy rooms).

Parasomnias. Parasomnias are undesirable sleep problems that occur while falling asleep, between sleep phases, or during transitions from sleep to wakefulness. The word *parasomnia* is derived from the Greek word *para* combined with the Latin word *somnus* meaning event accompanying sleep (Silvestri & Arico, 2008). The parasomnia may range from

BOX 40-5

Sleep Hygiene: Fundamental Principles

- Avoid late afternoon naps.
- Decrease consumption of caffeine, tobacco, and alcohol.
- Exercise regularly, but not prior to bedtime.
- Eat regular meals, do not go to bed hungry, and decrease consumption of liquids in the evening.
- Maintain a regular sleep-wake schedule, even on weekends.
- Maintain the bedroom as an environment solely for sleep.
- Ensure a sleeping environment that is comfortable and quiet.

abnormal sleep-related movements to emotions, perceptions, dreaming, or behaviours. Parasomnia may be the manifestation of an underlying physical or psychological disorder or may be caused by the ingestion of drugs or other substances (Lee-Chiong, Jr., 2008). Parasomnias are more common in children than in adults (Verrier & Josephson, 2011).

Parasomnias that occur among older children include somnambulism (sleepwalking), night terrors, nightmares, nocturnal enuresis (bedwetting), body rocking, and bruxism (teeth grinding). When adults experience these symptoms, more serious disorders are often indicated. Specific treatment for these disorders varies; however, in all cases patients need to be supported and their safety maintained.

Shift Work. *Shift work sleep disorder* (SWSD) is a common sleep disorder experienced by individuals who work outside the traditional 9-to-5 workday. Most commonly associated with nighttime work, the health and economic consequences of this disorder are profound. Studies suggest that individuals who engage in shift work have a high risk of developing cardiovascular disease. The most common problems reported by shift workers are excessive sleepiness, fatigue, and insomnia resulting from imposing a sleep-wake schedule that is contrary to the body's internal circadian clock. Not all individuals exposed to shift work develop this disorder (Drake & Wright, Jr., 2011).

Sleep Deprivation. Sleep deprivation refers to insufficient sleep during a specific time period. The most common causes of sleep deprivation are lifestyle factors or work-related factors. One approach to understanding the functional significance of sleep is to consider the behavioural and physiological effects of sleep deprivation. Numerous studies on animal models subjected to periods of sleep deprivation demonstrated that sleep deprivation resulted in changes in metabolism (weight loss despite increased food intake), impaired glucose metabolism, increased heart rate, skin lesions, decreased body temperature, and, with prolonged periods, death (Van Cauter et al., 2008).

There are several types of sleep deprivation. Sleep deprivation may be observed as a reduction in sleep time where sleep time does not meet the needs of the individual, prolonged wakefulness, and sleep disruption related to a pathophysiological process (e.g., cancer). The extent to which an individual experiences the effects of sleep deprivation depends on the physiological and behavioural requirements of the individual (Orezel-Gryglewska, 2009). Additionally, the effects of sleep deprivation are cumulative, meaning a mild reduction in sleep time over a prolonged period may be detrimental to the individual (Tibbitts, 2008).

Sleep deprivation may be experienced by individuals for a variety of reasons. Causes include illness (e.g., fever, difficulty breathing, or pain), emotional stress, certain medications, environmental disturbances (e.g., noise, unfamiliar surroundings, frequent nursing care), and variability in the timing of sleep due to shift work and travel. Factors contributing to sleep deprivation in hospitalized patients are outlined in Box 40-6. Physicians and nurses are particularly prone to sleep deprivation due to their long work schedules and rotating shifts (Elliott et al., 2011; Lei et al., 2009). Hospitalization, especially in intensive care units (ICUs), makes patients particularly vulnerable to periods of sleep deprivation. Constant environmental stimuli within the ICU, such as strange noises from equipment, invasive equipment and procedures, the frequent monitoring and care given by nurses, and continuous light,

lead to an inability to sleep. Numerous studies have confirmed that ICU patients frequently experience sleep deprivation (Drouot et al., 2008; Elliot et al. 2011).

A person's response to sleep deprivation is highly variable. Patients exhibit a variety of physiological and psychological symptoms (Box 40-7). The severity of symptoms is often related to the duration of sleep deprivation. The most effective treatment for sleep deprivation is the elimination or correction of factors that disrupt the sleep pattern. You play an important role in identifying patients' treatable sleep deprivation problems.

Nursing Knowledge Base

Sleep and Rest

When persons are at **rest**, they usually feel mentally relaxed, free from anxiety, and physically calm. Rest does not imply

► BOX 40-6

Causes of Sleep Deprivation in Hospitalized Patients

Environmental Factors

- Noise
- Uncomfortable bed and pillows
- Bright lights
- Pathophysiological factors
- Pain and discomfort
- Use of invasive equipment such as intravenous lines, nasogastric tubes

Emotional Factors

- Stress, worry
- Lack of control
- Lack of privacy
- Anxiety about procedures and outcomes of investigations

► BOX 40-7

Sleep Deprivation Symptoms

Physiological Symptoms

- Ptosis, visual disturbances such as blurred vision
- Clumsiness in fine motor skills
- Decreased reflexes
- Slowed response time
- Decreased reasoning and judgement
- Decreased auditory and visual alertness
- Cardiac arrhythmias
- Increased food intake
- Decreasing satiety
- Weight loss

Psychological Symptoms

- Easily distracted
- Confusion and disorientation
- Forgetfulness
- Increased sensitivity to pain
- Irritability, withdrawal, apathy
- Excessive sleepiness
- Poor concentration
- Agitation
- Hyperactivity
- Decreased motivation

inactivity, although rest is often thought of as the act of settling down in a comfortable chair or lying in bed. Usually, when individuals are at rest, they are in a state of mental, physical, and spiritual activity that leaves them feeling refreshed, rejuvenated, and ready to resume the activities of the day. Individuals have their own habits for obtaining rest and can adjust to new environments or conditions that affect their ability to rest. Rest is gained from reading a book, practising a relaxation exercise, listening to music, taking a long walk, or sitting quietly.

Illness and unfamiliar health care routines can easily affect the usual rest and sleep patterns of individuals entering a hospital or other health care facility. You may frequently care for patients on bedrest, which confines patients to the bed to reduce the physical and psychological demands on their body. Patients may not necessarily feel rested because they may still have emotional worries that prevent complete relaxation. For example, concern over physical limitations or a fear of being unable to return to their usual lifestyle can cause patients to feel stressed and unable to relax. You must always be aware of the patient's need for rest. Long periods without rest can lead to illness or to the worsening of an existing illness.

Normal Sleep Requirements and Patterns

Individual requirements for sleep duration and quality vary among individuals of all age groups. For example, one person may feel adequately rested after 6 hours of sleep, whereas another person may require 10 hours of sleep.

Neonates. During the first few weeks of life, newborns sleep about 16 hours a day, sleeping almost constantly during the first week. Sleep occurs equally across the day and night in newborns and is more strongly influenced by hunger than by light-dark cues. The sleep cycle of newborns is generally 40 to 50 minutes with waking occurring after one to two sleep cycles. Sleep is classified as active sleep (REM sleep equivalent) or quiet sleep (NREM sleep equivalent). A third stage has also been identified and is known as indeterminate sleep. This sleep stage cannot be defined as either quiet sleep or active sleep by polysomnography. Newborn sleep cycles begin with active sleep; newborns spend the majority of their sleep time in this stage of sleep. The primary function of active sleep is thought to allow for the continued development of neural pathways (Crabtree & Williams, 2009; Lee-Chiong, Jr., 2008).

Infants. By three months, the amount of time the newborn spends in active sleep (REM sleep equivalent) diminishes, the required hours for sleep gradually decrease, and sleep-wake periods develop into a day/night cycle. By six months of age, infants enter sleep through NREM sleep. The ability to sleep during the night develops by six to nine months of age. At this point, the infant's sleeping pattern is characterized by a nocturnal sleep period of 10 to 12 hours' duration, two to three daytime naps, which collectively amount to 12 to 14 hours of total sleep time. Awakening commonly occurs early in the morning, although awakening during the night is not unusual (Crabtree & Williams, 2009; Lee-Chiong, Jr., 2008).

Toddlers. By two years of age, most children usually require 12 to 14 hours of sleep each day, which generally includes a nap in the afternoon and, for some, a morning nap as well. This amount of sleep is needed to re-energize the toddler and for continued growth and development. Lack of sleep makes a toddler feel tired and irritable. Awakening during the night is common for toddlers. A variety of factors

may influence night waking, including dreams and a fear of being separated from their parents. During this period, the percentage of REM sleep continues to fall (Crabtree & Williams, 2009; Hockenberry & Wilson, 2007).

Preschoolers. A preschooler sleeps about 13 hours a night (about 20% of which is REM sleep). By five years of age, the preschooler rarely takes daytime naps, except in cultures where siestas are the custom (Hockenberry & Wilson, 2007). The preschooler usually has difficulty relaxing or quieting down after long, active days and may experience bedtime fears, waking during the night, or nightmares. Partial waking, followed by a normal return to sleep, is frequent (Hockenberry & Wilson, 2007). In the waking period, the child may exhibit brief episodes of crying, walking aimlessly, unintelligible speech, sleepwalking, or bedwetting. Numerous factors may influence the sleep pattern of preschoolers, including day care and preschool schedules, family routines, and parental expectations as to the amount of sleep required for this developmental stage (Crabtree & Williams, 2009).

School-Aged Children. The amount of sleep needed varies during the school-age years. Both gender and ethnicity may explain the variability of sleep patterns in school-aged children. A longer sleep cycle has been observed in school-aged girls compared with their same-aged male counterparts. Caucasian children have more NREM stage 1 sleep and less NREM stage 2 sleep than African American children. Most school-aged children sleep between 9 and 10 hours each night. Epidemiological studies of school-aged children have shown shorter sleep times are associated with behavioural problems and symptoms of depression (Paavonen et al., 2009; Seo et al., 2010).

Adolescents. The sleep pattern of adolescents is variable across a seven-day week, with shorter sleep times occurring during the school week. Consecutive nights of shorter sleep results in "sleep debt," with adolescents recovering this sleep on weekends with longer sleep times. The demands of school (e.g., schedules, assignments, exams, and extracurricular activities), decreased parental influence, and employment appear to play a significant role in the sleep patterns of adolescents. Physiological (circadian and homeostatic) processes that regulate sleep and wakefulness are also thought to influence the sleep habits of adolescents (Crabtree & Williams, 2009; Lee-Chiong, Jr., 2008). This shortened sleep time often results in excessive daytime sleepiness (EDS). As a result of EDS, adolescents may experience reduced performance in school, vulnerability to accidents, behaviour and mood problems, and increased use of alcohol or other substances (Crabtree & Williams, 2009; Gradisar et al., 2011).

Young Adults. Most young adults average 6 to 8.5 hours of sleep per night. Approximately 20% of sleep time is REM sleep, which remains consistent throughout life. The stresses of the job, family relationships, and social activities frequently lead to both insomnia and the use of medications to aid sleep. Daytime sleepiness contributes to an increased number of accidents, decreased productivity, and interpersonal problems in this age group. Pregnancy increases the need for sleep and rest. During the third trimester of pregnancy, women may experience insomnia, periodic limb movements, restless leg syndrome, and sleep disordered breathing (Balserak & Lee, 2011).

Middle Adults. During middle adulthood, the total time spent sleeping at night begins to decline. The amount of stage 4 sleep begins to fall and continues to fall with advancing age. Insomnia is particularly common, probably because of the

changes and stresses experienced in middle age. Anxiety, depression, and certain physical illnesses cause sleep disturbances. Women who have menopausal symptoms often experience insomnia (Lee & Moe, 2011).

Older Adults. Aging results in several physiological and psychological changes, and alterations in sleep patterns frequently occur because of these changes. Studies suggest that poor sleep quality is a common complaint of older adults. Approximately 50% of older adults report difficulty sleeping (Espiritu, 2008; Neikrug & Ancoli-Israel, 2010; Roepke & Ancoli-Israel, 2010). Aging is associated with changes in **sleep architecture**, or sleep pattern. Greater nighttime disturbances (increased awakenings at night), less slow-wave or deep sleep, increased frequency of daytime napping, and decreased total sleep time are changes in sleep architecture that occur with aging (Lee-Chiong, Jr., 2008).

Older women are at particular risk for sleep problems due to hormonal changes that accompany menopause. In fact, problems sleeping are reported by approximately 25% to 50% of menopausal women (Roepke & Ancoli-Israel, 2010). Hot flashes (episodes of warmth in the face and chest) occurring at night can cause problems sleeping and may lead to an increase in the frequency of nighttime awakenings and hence less sleep time.

Numerous factors are related to the sleep problems reported by older men and women. These include presence of co-morbid physiological conditions (e.g., heart disease) and psychological conditions (e.g., depression), primary sleep disorders (e.g., insomnia), chronic pain, nocturia, hormonal changes, use of multiple medications, and alterations in circadian rhythm expressions (Neikrug & Ancoli-Israel, 2010).

Factors Affecting Sleep

Often, several factors alter the quality and quantity of sleep, such as physiological, psychological, and environmental influences.

Drugs and Substances. Many older adults take a variety of medications to control or treat chronic conditions, and these medications can seriously disrupt sleep. Daytime sleepiness, insomnia, and fatigue often result as a direct effect of commonly prescribed medications (see Box 40-8). These medications may impair waking function and alter sleep patterns, which can be problematic for individuals (Cook, 2008a, 2008b; Smith et al., 2008). Antidepressants, antihistamines, and pain medications can cause daytime sleepiness or fatigue. Beta blockers have been associated with nightmares and vivid dreams. Diuretics can cause nocturia, thereby disrupting sleep. Medications prescribed for sleep can also be problematic as a result of their sedating effects during daytime hours (Mendelson, 2011).

Lifestyle. A person's daily routine influences sleep patterns. An individual working a rotating shift (e.g., two weeks of day shifts followed by a week of night shifts) often has difficulty adjusting to the altered sleep schedule (National Sleep Foundation, 2009b). For example, the body's internal clock for bedtime is set at 11 P.M., but the work schedule instead forces sleep at 9 A.M. The individual is able to sleep only three or four hours because the body's clock perceives that the morning is the time to be awake and active. Difficulties with maintaining alertness during work time result in decreased and even hazardous performance. After several weeks of working a night shift, a person's biological clock usually does adjust. Other alterations in routines that disrupt sleep patterns are

► BOX 40-8

Drugs and Their Effect on Sleep and Wakefulness

Hypnotics

- Decrease NREM stages 3 and 4 sleep as well as REM sleep
- Increase daytime sleepiness
- Lead to poor memory and concentration
- Depress respirations
- May worsen sleep apnea in older adults

Diuretics

- Nighttime awakenings caused by nocturia

Antidepressants

- Cognitive impairment
- Psychomotor impairment
- Increase of NREM stage 1 sleep
- Suppression of REM sleep
- Decrease in total sleep time
- Daytime sleepiness

Stimulants

Caffeine

- Prevents the onset of sleep
- Interrupts sleep during the night
- Decreases the time spent in deep sleep
- Interferes with REM sleep

Alcohol

- Speeds onset of sleep
- Reduces REM sleep
- Interrupts sleep during the night and makes returning to sleep difficult

Beta-Adrenergic Blockers

- Fatigue
- Insomnia
- Depression
- Psychomotor impairment
- Nightmares
- Vivid dreams

Benzodiazepines

- Alter REM sleep
- Increase sleep time
- Increase daytime sleepiness

Narcotics

- Cause somnolence
- Decrease amount of time spent in deep sleep stages
- Suppress REM sleep
- Depress respirations
- Cause cognitive impairment
- Cause psychomotor impairment

Anticonvulsants

- Decrease REM sleep time
- May cause daytime drowsiness
- May cause insomnia
- Cause impaired cognition

Anti-Parkinsonian Drugs

- May cause worsening of cognitive function, especially memory
- Cause fatigue
- Cause somnolence

performing unaccustomed heavy work, engaging in late-night social activities, and changing the evening mealtime (Balkin, 2011; Belenky & Akerstedt, 2011).

Usual Sleep Patterns. In the past century, the amount of sleep obtained nightly has decreased by more than 20% (National Sleep Foundation, 2010), which indicates that many adults are sleep deprived and experience excessive sleepiness during the day. Sleepiness becomes pathological when it occurs at times when individuals need to or want to be awake. Individuals who experience temporary sleep deprivation as a result of an active social evening or a lengthened work schedule usually feel sleepy the next day. However, they are usually able to overcome these feelings despite the difficulty they experience in performing tasks and remaining attentive. Much more serious than temporary sleep deprivation is chronic lack of sleep, which causes serious alterations in the ability to perform daily functions. Sleepiness tends to be most difficult to overcome during the performance of sedentary (inactive) tasks. For example, single-vehicle accidents related to a driver falling asleep at the wheel occur most often between 2 A.M. and 5 A.M., as a result of the sleepiness that occurs when individuals are awake during what is their normal period of sleep (Philip et al., 2011).

Emotional Stress. Sleep is frequently disrupted by worry over personal problems or a personal situation. **Emotional stress** causes a person to be tense and often leads to frustration when sleep does not occur. Stress also causes a person to try too hard to fall asleep, to awaken frequently during the sleep cycle, or to oversleep. Continued stress can lead to poor sleep habits.

Older patients frequently experience personal losses, such as retirement, physical impairment, or the death of a loved one, all of which can lead to emotional stress. Older adults and other individuals who live with depressive mood problems may experience delays in falling asleep, the earlier appearance of REM sleep, frequent awakening, increased total bed time, feelings of having slept poorly, and early awakening (National Sleep Foundation, 2009b).

Environment. The physical environment in which a person sleeps can significantly influence the ability to fall asleep and remain asleep. Good ventilation is essential for restful sleep. The size, firmness, and position of the bed also affect the quality of sleep. If a person usually sleeps with another individual, sleeping alone often causes wakefulness. On the other hand, sleeping with a restless or snoring bed partner can disrupt sleep.

In hospitals and other inpatient facilities, noise creates a problem for patients. Noise in hospitals is usually new or strange and often loud, and patients wake easily. While in hospital, the sleep of patients is often fragmented with patients experiencing increased total wake times, increased nocturnal awakenings, and decreased REM sleep and total sleep time. Environment-induced noises (e.g., nursing activities) are sources of increased sound levels. Intensive care units are sources for high noise levels as the result of staff consultations, monitor alarms, and equipment sounds (Elliott et al., 2011). The environment is unpleasant for sleeping because of the close proximity of patients, noise from confused and ill patients, the ringing of alarm systems and telephones, and disturbances caused by emergencies. Noise contributes to hearing loss, delays healing, impairs the immune function, and increases blood pressure, heart rate, and stress (Patel, Chipman, et al., 2008).

The level of light in a room affects the ability to fall asleep. Some patients prefer a dark room for sleep, whereas others, such as children or older adults, often prefer soft lighting during sleep. Patients may also have trouble sleeping because of the temperature of a room. A room that is too warm or too cold often causes a patient to become restless.

Exercise and Fatigue. A person who is moderately fatigued usually achieves restful sleep, especially when the fatigue is the result of enjoyable work or exercise. Exercising that is completed at least three hours prior to bedtime allows the body enough time to cool down and maintains a state of fatigue that promotes relaxation (National Sleep Foundation, 2009a). However, excess fatigue resulting from exhausting or stressful work makes falling asleep difficult. Excess fatigue is a common problem for grade-school children and adolescents.

Food and Caloric Intake. Following good eating habits is important for proper sleep. Eating a large, heavy meal or a spicy meal at night often leads to indigestion that interferes with sleep. Insomnia can result from caffeine, alcohol, or nicotine consumed in the evening. Coffee, tea, cola, and chocolate contain caffeine and xanthines that cause sleeplessness. Individuals who have insomnia can improve their sleep by drastically reducing or completely avoiding these substances (Reeve & Bailes, 2010). Some food allergies cause insomnia. In infants, a milk allergy sometimes causes nighttime waking and crying, or colic.

Both weight loss and weight gain influence sleep patterns (Patel, 2009; Van Cauter et al., 2008). Weight gain contributes to obstructive sleep apnea because of the increased size of the soft tissue structures in the upper airway (Wellman & White, 2011). Weight loss causes insomnia and decreased amounts of sleep (Patel, 2009). Certain sleep disorders are the result of the semistarvation diets popular in a weight-conscious society.

Critical Thinking

Successful critical thinking requires a synthesis of knowledge, including information gathered from patients, past experience, critical thinking qualities, and intellectual and professional standards. Clinical judgements require you to anticipate the required information, analyze the data, and make decisions regarding patient care. Adapting to the changing needs of your patient, based on sound decision making, constitutes critical thinking. During your assessment (Figure 40-3), consider all elements to make appropriate nursing diagnoses.

In the case of sleep, you will integrate knowledge from disciplines such as nursing, pharmacology, and psychology. Your experience with patients who have sleep problems, coupled with exploring research related to sleep, will aid in your understanding of effective forms of sleep therapies. You will need to use critical thinking qualities, such as perseverance, confidence, and discipline to complete a comprehensive assessment and to develop a plan of care that can successfully manage the sleep problem. The framework for practice developed by the Canadian Nurses Association (2007) and standards of practice developed by each provincial and territorial nursing organization identify your role as a nurse in patient care. In addition, evidence-informed geriatric nursing protocols for best practice such as those in *Excessive Sleepiness* (Chasens et al., 2008) provide specific instructions for assessing and addressing the needs of older patients with sleep disorders.

Figure 40-3 Critical thinking model for sleep assessment.

Nursing Process

◆ Assessment

Assess patients' sleep patterns by using the nursing history to gather information about factors that usually influence sleep. Because sleep is a subjective experience, only the patient is able to report whether it is sufficient and restful. If the patient is satisfied with the quantity and quality of sleep received, you will consider it normal, and the nursing history is brief. If, however, a patient reports or suspects a sleep problem, you need to conduct a detailed history.

Sleep Assessment

Most individuals are able to provide a reasonably accurate estimate of their sleep patterns, particularly if any changes have occurred. In your assessment, focus on understanding the characteristics of the patient's sleep problem and usual sleep habits so that your nursing care strategies to promote sleep are individualized. For example, if the nursing history reveals that a patient always reads before falling asleep, then offer reading material at bedtime.

Sources for Sleep Assessment. Usually, patients are the best resource for describing their sleep problems and how these problems differ from their usual sleep and waking patterns. The patient often knows the cause of sleep problems, such as a noisy environment or worry over a relationship. In

addition, bed partners are able to provide information on the patient's sleep patterns that help gain insight regarding the nature of certain sleep disorders. For example, partners of patients with sleep apnea often complain that the patient's snoring disturbs their sleep. Often the partners must sleep in a different bed or move to another room to obtain adequate sleep. Ask bed partners whether patients have pauses of breathing during sleep and how frequently these pauses occur. Some partners mention becoming fearful when patients stop breathing during sleep.

When caring for children, seek information about sleep patterns from the parents, who are usually a reliable source of information about their child's trouble with sleeping.

An infant's difficulty in falling asleep or frequent awakenings during the night are often the result of hunger, excessive warmth, or separation anxiety. Parents of infants need to keep a 24-hour diary of their infant's waking and sleeping behaviour for several days to aid in determining the cause of the problem. Ask the parents to describe the infant's eating pattern and sleeping environment, both of which can influence sleeping behaviour. Older children often are able to verbalize the fears or worries that inhibit their ability to fall asleep. If children frequently awaken in the middle of bad dreams, parents may be able to identify the problem, although they may not be able to understand the meanings of the dreams. Ask parents to describe the typical behaviour patterns that foster or impair sleep. For example, excessive stimulation from active play or from visiting friends will predictably impair sleep. In the case of a child who experiences chronic sleep problems, ask the parents to describe provoking factors, the duration of the problem, its progression, and the child's responses.

Tools for Sleep Assessment. Although subjective reports of sleep are reliable and valid measures of sleep, some people may be inclined to exaggerate or minimize their sleeping patterns. One effective, brief method for assessing sleep quality is the use of a visual analogue scale (Chervin, 2011; Cohen, 2004). Draw a straight horizontal line 100 mm long. At the opposite ends of the line, print two opposing statements, such as "best night's sleep" and "worst night's sleep." Ask patients to mark a point on the horizontal line that corresponds to their perception of the previous night's sleep. Measure the distance of the mark along the line in millimetres; this number is a numerical value for satisfaction with sleep. Use the scale repeatedly to show change over time. Such a scale is useful to assess an individual's changes in sleep pattern over time.

Another brief subjective method to assess sleep is a numeric scale with a 0 to 10 sleep rating (Cohen, 2004). Instruct patients to first rate their sleep quantity, then their quality of sleep on a scale of 1 to 10, with 0 being the worst sleep and 10 being the best sleep.

Sleep History

When a patient reports having received adequate sleep, a sleep history is usually brief. The information needed for you to plan care conducive to sleep includes the following: the usual bedtime, bedtime rituals, the preferred environment for sleeping, and the time the patient usually rises. When you suspect a sleep problem, explore the quality and characteristics of sleep in greater depth by asking patients to describe the nature of their sleep, including recent changes in their sleep pattern, sleep symptoms experienced during waking hours, use of sleep medications and other prescribed or over-the-counter

medications, herbal products, diet, intake of substances such as caffeine or alcohol that influence sleep, and recent life events that may have affected the patient's mental well-being.

Description of Sleeping Problems. When a patient reports a sleep problem, you need to conduct a more detailed history. A detailed assessment ensures that the appropriate therapeutic care is provided. Open-ended questions help a patient to describe the problem more fully. After the patient provides a general description of the problem, you can ask some focused questions, which will usually reveal specific characteristics that are useful in planning therapies. You need to understand the nature of the sleep problem, its signs and symptoms, its onset and duration, its severity, any predisposing factors or causes, and the overall effect on the patient. Ask specific questions related to the sleep problem (Box 40-9).

► BOX 40-9 Nursing Assessment Questions

Nature of the Problem

What type of problem are you having with your sleep?

Why do you think your sleep is inadequate?

Describe for me a recent typical night's sleep. How is this sleep different from what you are accustomed to?

Signs and Symptoms

Do you have difficulty falling asleep, staying asleep, or waking up?

Have you been told that you snore loudly?

Have you been told you stop breathing or gasp for breath during sleep?

Do you feel drowsy or fall asleep while reading, when watching television, while driving, or when participating in other daily activities?

Do you feel excessively sleepy or irritable? Do you have trouble concentrating during waking hours? Do you have headaches when awakening? Does your child awaken from nightmares?

Onset and Duration

When did you notice the problem?

How long has this problem lasted?

Severity

How long does it take you to fall asleep?

How often during the week do you have trouble falling asleep?

How many hours of sleep a night did you get this week?

How does this amount of sleep compare to what is usual for you?

What do you do when you awaken during the night or when you awaken too early in the morning?

Predisposing Factors

What do you do just before you go to bed?

Have you recently had any changes at work or at home?

Describe your mood. Have you noticed any changes in your mood recently?

What recreational drugs do you take on a regular basis?

Are you taking any new prescription or over-the-counter medications?

Do you eat food (spicy or greasy foods) or drink substances (alcohol or caffeinated beverages) that interfere with your sleep?

Do you have a physical illness that interferes with your sleep?

Does anyone in your family have a history of sleep problems?

Effect on the Patient

How has the loss of sleep affected you?

Proper questioning helps to determine the type of sleep disturbance and the nature of the problem. Box 40-10 gives examples of additional questions for you to ask the patient when you suspect specific sleep disorders. The questions assist in selecting specific sleep therapies and the best time for implementation.

As an adjunct to the sleep history, have the patient and the patient's bed partner keep a sleep-wake diary for one to four weeks (Lee-Chiong, Jr., 2008). The patient completes the sleep-wake diary daily to provide information on day-to-day variations in sleep-wake patterns over extended periods. Entries in the diary can include 24-hour information about various waking and sleeping health behaviours, including evening and bedtime routines, the time the patient goes to bed, the amount of time it took for the patient to fall asleep, the number of awakenings during the night, total sleep time, sleep quality (did they feel rested in the morning), the time and length of daytime napping, mealtimes, type and amount of alcohol and caffeine consumed, current medications, and daytime activities. A partner helps to record the estimated times the patient falls asleep or awakens. Although the sleep diary can provide useful information, the patient needs to be motivated to participate in recording the entries.

► BOX 40-10 Questions to Ask to Assess for Specific Sleep Disorders

Insomnia

Do you have difficulty falling asleep?

After you fall asleep, do you have difficulty staying asleep? How many times during a night's sleep do you awaken?

When you wake up in the morning, do you feel rested? What time do you wake up in the morning? What causes you to awaken early?

What do you do to prepare for sleep? What do you do to improve your sleep?

What do you think about as you try to fall asleep?

When did you notice you had problems sleeping?

How often do you have trouble sleeping?

Do you feel excessively tired or sleepy during the day?

Do you take naps during the daytime?

Do you have any problems with performing tasks (i.e., work-related or driving) during the daytime?

Sleep Apnea

Do you snore loudly? Does anyone else in your family snore loudly?

Has anyone (e.g., spouse, bed partner, roommate) ever told you that you stop breathing for short periods during your sleep?

Do you experience headaches after awakening?

Do you have difficulty staying awake during the day?

Narcolepsy

Do you sometimes fall asleep unexpectedly? (Friends or relatives may report any occurrences.)

Do you feel excessively tired or sleepy during the day?

Do you have trouble concentrating?

Have you ever had an episode of losing muscle control or falling to the floor after a laughing episode or when angry?

Have you ever had the feeling of being unable to move or talk just before falling asleep or upon awakening?

Do you have vivid dreams when going to sleep or waking up?

Usual Sleep Pattern. What constitutes “normal sleep” is difficult to define because individuals vary in their perception of the adequate quantity and quality of sleep. It is the responsibility of all health care providers to inquire about sleep quality of all patients. Patients need to describe their usual sleep pattern to determine the significance of the changes caused by a sleep disorder. Ask the following questions to determine a patient’s sleep pattern:

1. What time do you usually go to bed each night?
2. What time do you usually fall asleep? Do you do anything special to help you fall asleep?
3. How many times do you awaken during the night? Why?
4. What time do you typically wake in the morning?
5. What is the average number of hours you sleep each night?

Compare the patient data with the predominant sleep pattern for other patients of the same age. On the basis of this comparison, you can begin to assess for identifiable patterns, which may indicate a specific sleep disturbance, such as insomnia.

Patients with sleep problems frequently show patterns that differ drastically from their usual sleep pattern, or sometimes the change is relatively minor. Hospitalized patients usually need or want more sleep as a result of their illness; however, some patients require less sleep because they are less active. Some patients who are ill think that they need to try to sleep more than their usual amount of sleep, a perception that eventually makes sleeping difficult.

Physical and Psychological Illness. Determine whether the patient has any preexisting health problems that interfere with sleep. Poor sleep quality has been associated with numerous physiological and psychological illnesses. Chronic diseases, such as chronic obstructive pulmonary disease, and painful disorders, such as arthritis, interfere with sleep. This may occur because of the conditions themselves or because of medications taken to treat them. Several symptoms associated with these conditions, such as shortness of breath, pain, and nocturia, can potentially disrupt sleep. Psychiatric disorders can also interfere with sleep. For example, insomnia is common in individuals with schizophrenia, a chronic psychiatric disorder.

Insomnia is also common among individuals with depression. Anxiety disorders have also been associated with poor sleep (Ramsawh et al., 2011). Hence, it is very important to assess patients’ sleep pattern, medical and social history (e.g., alcohol, tobacco, and caffeine consumption), and medication usage, including a description of over-the-counter and prescribed drugs. The social history can provide useful information such as, for example, about a situational crisis that may be interfering with sleep. If a patient takes medications to aid sleep, gather information about the type and amount of medication that the patient uses. Assess the effectiveness of any medication and their effects on daytime function (Lee-Chiong, Jr., 2008).

Current Life Events. During your assessment, ask whether the patient is experiencing any changes in lifestyle that could disrupt sleep. A person’s occupation often offers a clue to the nature of the sleep problem (Drake & Wright, Jr., 2011). Changes in job responsibilities, rotating shifts, or long hours contribute to a sleep disturbance. You can question the patient about social activities, recent travel, or mealtime schedules to help clarify the sleep assessment.

Bedtime Routines. Ask patients what they do to prepare for sleep. For example, the patient may drink a glass of milk,

take a sleeping pill, eat a snack, or watch television. Note the habits that are beneficial compared with those that disturb sleep. For example, watching television may promote sleep for one person, whereas watching TV may stimulate another person to stay awake. Sometimes pointing out that a particular habit is interfering with sleep helps patients to find ways to change or eliminate that habit.

Pay special attention to a child’s bedtime rituals. Parents need to report whether it is necessary, for example, to read the child a bedtime story, rock the child to sleep, or engage in quiet play. Some young children need a special blanket or stuffed animal when going to sleep.

Bedroom Environment. During your assessment, ask the patient to describe their preferred bedroom conditions. These preferences may be the lighting in the room, music or television in the background, or the need to have the bedroom door open or closed. Some children require the company of a parent to fall asleep. In a health care environment, environmental distractions often interfere with sleep, such as a roommate’s television, an electronic monitor in the hallway, a noisy nurses’ station, or another patient who cries out at night. Identify strategies that you or the patient can use to reduce the effects of the distractions or to control the environment.

Behaviours of Sleep Deprivation. Some patients are unaware of how their sleep problems affect their behaviour. Observe the patient for behaviours such as irritability, forgetfulness, confusion, lethargy, frequent yawning, and slurred speech. If sleep deprivation has lasted a long time, psychotic behaviour, such as delusions and paranoia, sometimes develop. For example, a patient may report seeing strange objects or colours in the room, or the patient may act afraid when a nurse enters the room.

Patient Expectations

When a patient experiences a poor night’s sleep, a vicious cycle of anticipatory anxiety may begin. The patient may fear that sleep will again be disturbed and will try harder and harder to sleep (Morin, 2011). When assessing the patient’s sleep needs, use a skilled, individualized, and caring approach. Always ask patients what they expect regarding their sleep, the interventions they currently use, and the success of these interventions. Inquire about what other interventions they may prefer, and how they could be implemented. It is important to understand the patients’ expectations regarding their sleep pattern. When patients ask for assistance because of sleep disturbances, they typically expect a nurse to respond promptly to assist them in improving their quantity and quality of sleep.

❖Nursing Diagnosis

Review your assessment to identify clusters of data that characterize a sleep pattern disturbance. If you identify a sleep pattern disturbance, be specific, as numerous factors may be the cause of these disturbances. By specifying the nature of a sleep disturbance and related factors, you will be able to develop with the patient interventions particular to the patient’s situation. For example, interventions developed for sleep apnea will differ from those interventions developed to address sleep pattern disturbances related to psychological distress (e.g., anxiety, stress). Box 40-11 demonstrates how to use nursing assessment activities to identify and cluster defining characteristics to make an accurate nursing diagnosis related to sleep pattern disturbances.

► BOX 40-11 NURSING DIAGNOSTIC PROCESS

Insomnia

Assessment Activities

Ask the patient to describe his or her sleep pattern (past and present), the nature of the sleep problem, duration, etc.

Defining Characteristics

The patient reports either a history of or no history of sleep problems. The patient reports difficulty in falling asleep, staying asleep, and awakening several times during the night. Once awakened, the patient reports difficulty returning to sleep.

The patient reports the need to nap during the day due to daytime sleepiness.

With the use of a visual analogue scale, the patient reports feeling fatigued following a night's sleep.

The patient reports no regular bedtime routine and frequently remains in bed in the morning to "catch up" on the sleep lost the previous night.

Related Factors

Pathophysiological	The patient reports frequent awakenings during the night, for example, due to problems breathing.
Treatment	The patient reports daytime sleepiness due to medication.
Situational (personal, lifestyle)	The patient reports difficulty falling asleep and staying asleep because of a personal crisis. For example, the loss of a patient's job; the patient reports problems sleeping related to a recent diagnosis of cancer.
Observe the patient's appearance	The patient appears pale and has dark circles under the eyes.
Observe the patient's behaviour, and ask the patient's spouse whether the patient is experiencing behavioural changes.	The patient is irritable and yawns frequently. The patient reports not feeling well-rested and poor concentration. The spouse describes times when the patient was lethargic and distracted. The patient and the patient's spouse report napping during the day.
Determine whether the patient has experienced recent lifestyle changes.	The spouse reports the patient recently lost his or her job and is concerned about finding a new position. The patient reports being under tremendous stress because of a family member's illness.

Many factors can contribute to disturbed sleep patterns. It is important that your assessment identifies the probable cause of or factors related to the sleep disturbance, such as a noisy environment, a situational crisis, or a high intake of caffeinated beverages in the evening. These causes become the focus of interventions for minimizing or eliminating the problem. For example, if a patient is experiencing insomnia as the result of a noisy health care environment, use strategies to promote sleep, such as controlling the noise of hospital equipment, reducing interruptions, or keeping doors closed. If the insomnia is related to worry over a threatened marital separation, introduce coping strategies and collaborate with other health care providers regarding support groups or other services available to support the patient (Carpenito-Moyet, 2008; Lei et al., 2009). If you incorrectly identify the probable cause or related factors, the patient will not benefit from the strategies to minimize or eliminate the presumed sources of disruption.

Sleep problems affect patients in other ways. For example, you may find that a patient with sleep apnea is in conflict with a spouse who is tired of and frustrated over the patient's snoring. In addition, the spouse may be concerned that the patient is breathing improperly and thus is in danger. The nursing diagnosis of *compromised family coping* indicates that you need to provide support to both the patient and the patient's spouse so that they both understand sleep apnea and obtain the medical treatment needed. The following are examples of nursing diagnoses for patients with sleep problems:

- *Anxiety*
- *Ineffective breathing pattern*
- *Acute confusion*
- *Compromised family coping*
- *Ineffective coping*
- *Ineffective health maintenance*
- *Fatigue*
- *Ineffective protection*
- *Insomnia*
- *Disturbed sensory perception*
- *Sleep deprivation*

❖ Planning

Goals and Outcomes

During your planning of a strategy of care, you again synthesize information from multiple resources to develop an individualized plan of care (Figure 40-4 and Box 40-12). Ensure you consider standards of nursing practice and clinical practice guidelines when developing a plan of care. Clinical practice guidelines are evidence-informed recommendations developed by expert practitioners and arise from a synthesis of the best evidence of a particular topic (Morin, 2011).

As you plan care for the patient with sleep problems, you can create a concept map to help develop a holistic approach to patient-centred care (Figure 40-5). Create the concept map after identifying the relevant nursing diagnoses from the assessment database. In this example, the nursing diagnoses

Figure 40-4 Critical thinking model for sleep planning.

are linked to the patient's anxiety related to her mother's recent cancer diagnosis.

The concept map shows the relationships between the nursing diagnoses *anxiety*, *disturbed sleep pattern*, and *impaired social interaction*. This approach to planning care can assist you in recognizing relationships between planned interventions. For this patient, interventions and successful outcomes for one nursing diagnosis affect the resolution of another nursing diagnosis.

When developing goals and outcomes, you and the patient need to collaborate. As a result, you will be more likely to set realistic goals and measurable outcomes. An effective plan includes outcomes that focus on the goal of improving the quantity and quality of sleep in the home over a realistic period of time. Family members are often very helpful in contributing to the plan. A sleep promotion plan frequently requires many weeks to accomplish. The following is an example of a goal with patient outcomes:

Goal: The patient will control the environmental sources that disrupt sleep within one month.

Outcomes:

- The patient will identify factors in the immediate home environment that disrupt sleep within two weeks.
- The patient will report having a discussion with family members about environmental barriers to sleep within two weeks.
- The patient will report changes made in the bedroom to promote sleep within four weeks.
- The patient will report having fewer than two awakenings per night within four weeks.

BOX 40-12 NURSING CARE PLAN

Disturbed Sleep Pattern

Assessment

Andree Smith is a 36-year-old lawyer who presents to the health care centre where you are working. Andree, accompanied by her husband, has come to the clinic because she is having problems sleeping. Andree is married and has three children, two in school and one in preschool. As you begin your assessment, Andree suddenly bursts into tears and tells you her mother has been recently diagnosed with breast cancer. Andree's assessment includes a thorough sleep history and a discussion on how this sleep problem is affecting her life. A physical examination is also conducted.

Assessment Activities

Sleep pattern (present and past)

Findings and Defining Characteristics*

Andree reports difficulty falling asleep at night and awakening several times during the night. Andree states, "I am so tired; I have no energy to do anything. I am irritable all of the time and I am having trouble concentrating at work."

Andree also reports that she has less patience with her children.

Relational Factors

Pathophysiological

Assess whether Andree has a history of and/or a family history of sleep problems.

Assess whether Andree has a history of medical or psychiatric disorders.

Andree reports no personal or family history of sleep problems.

Andree reports she has no history of any medical or psychiatric disorders.

Treatment

Assess Andree's use of medications (both over-the-counter and prescription), including names, dosage, and frequency.

Andree reports she recently started taking melatonin at bedtime to help her sleep. Aside from melatonin, Andree is on no other medication.

Continued

► BOX 40-12 NURSING CARE PLAN—cont'd

Situational (personal, home, community)

Ask Andree whether she has had any recent changes in her life.

Andree reports being highly anxious and states, *"Everything bothers me."* She also reports that she has *stopped* her routine of walking 2–4 km daily because she has no energy.

Situational (personal, lifestyle)

Ask Andree to describe her bedtime routine.

Andree reports she is going to bed between midnight and 1 A.M., which is two hours later than her usual bedtime. *It takes her an hour to fall asleep.* In the past, she received 7–8 hours of sleep each night, but now *it is closer to 5–6 hours.* She drinks two to three cups of coffee after dinner while surfing the Internet for information on her mother's condition. Andree also reports drinking a glass of wine before bedtime to help her relax because she has been having trouble falling asleep.

Observe Andree's appearance.

Assess Andree for signs of sleep problems.

Observe Andree's behaviour.

Andree appears *pale and tired.* She has *dark circles under her eyes* and is *slow to respond* to questions asked. She *yawns* frequently during the interview and appears restless.

With Andree's permission, ask her husband whether Andree has exhibited any behavioural changes.

Andree's husband reports she is *irritable* with the children, is *forgetful*, and cries easily.

*Defining characteristics are in italic type.

Nursing Diagnosis: Insomnia related to psychological stress from mother's recent cancer diagnosis.

Planning

Goals (Nursing Outcomes Classification)*

Sleep

Andree will achieve an improved sense of restorative sleep within two weeks.

Andree will report adherence to a regular bedtime routine within one week.

Expected Outcomes

Andree will report waking less during the night and feeling rested within two weeks.

Andree will achieve a more normal sleep pattern within two weeks. Within two weeks, Andree will report sleeping seven hours nightly.

Within two weeks, Andree will fall asleep within 30 minutes of going to bed.

*Outcomes from Carpenito-Moyet, L. J. (Ed). (2008). *Nursing diagnosis: Application to clinical practice* (12th ed). New York: Lippincott Williams & Wilkins.

Interventions (Nursing Interventions Classification)*

Sleep Enhancement

Encourage Andree to establish a bedtime routine and a regular sleep pattern.

Maintaining a consistent schedule helps induce sleep (Milner & Belicki, 2010).

Instruct Andree to limit her consumption of caffeine, nicotine, and alcohol before bedtime.

Caffeine and nicotine are stimulants and cause difficulty in falling asleep. Alcohol has the effect of lightening and fragmenting sleep (Milner & Belicki, 2010).

Assist Andree in identifying ways to eliminate stressful concerns about work before bedtime (e.g., taking time before actual sleep time to read a light novel).

Excess worry and intense activities before bedtime may stimulate the patient and prevent sleep (National Sleep Foundation, 2009a).

Adjust the sleep environment: have Andree control the noise, temperature, and light in the bedroom.

Develop an environment conducive to sleep (Morin et al., 2007).

Exercise Promotion

Encourage Andree to begin walking routinely during the day, but not two to three hours before bedtime.

Regular exercise increases activity levels and improves sleep quality. When exercise occurs just before bedtime, it can act as a stimulant that prevents sleep (National Sleep Foundation, 2009a).

Simple Relaxation Therapy

Instruct the patient on how to perform muscle relaxation before bedtime.

Relaxation therapy can help to reduce anxiety, which interferes with sleep (Lee-Chiong, Jr., 2008).

*Intervention classification labels from Carpenito-Moyet, L. J. (Ed). (2008). *Nursing diagnosis: Application to clinical practice* (12th ed). New York: Lippincott Williams & Wilkins.

BOX 40-12 NURSING CARE PLAN—cont'd

Evaluation

Nursing Actions

Ask Andree whether she is able to fall asleep and stay asleep.

Ask Andree to describe her waking behaviours at work and home during the day.

Observe Andree's waking nonverbal expressions and behaviour.

Patient Response and Finding

Andree responds, "It usually takes me 15 to 20 minutes to fall asleep, and I woke up once at night twice last week."

Andree responds that she is able to concentrate on her work more. She reports she is less irritable with her children. She has restarted her walking routine.

Andree sits in the chair without shifting position. She actively engages in conversation with you. She does not yawn during the interview. She is not as pale as she was previously and the circles under her eyes are almost gone.

Achievement of Outcome

Andree reports she falls asleep within 30 minutes and wakes up less frequently during the night.

Andree reports feeling more rested.

Andree says she sleeps for an average of seven hours a night.

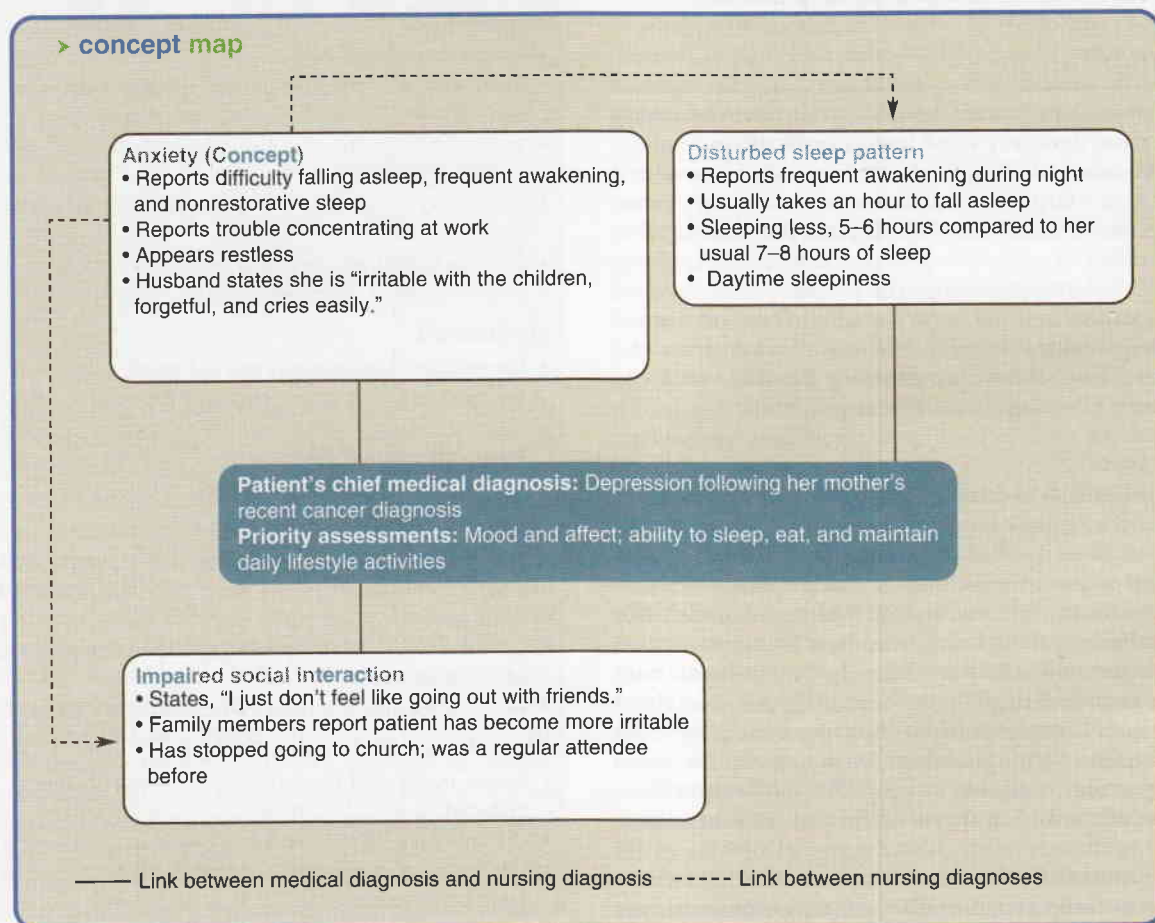

Figure 40-5 Concept map for a patient who has depression following the news of her mother's recent cancer diagnosis.

Setting Priorities

Collaborate with the patient to establish the priority outcomes and interventions. Remember, sleep problems are frequently the result of other health problems, and management of these problems and their associated symptoms is your first priority. Once the symptoms are properly managed, you can then focus on sleep therapies.

Collaborative Care

In collaboration with the patient and the patient's significant others, ensure that any planned interventions, such as a change in the sleep schedule or changes to the bedroom environment, are realistic and achievable. In a health care setting, plan the treatments or routines so that the patient is able to rest. For example, in the intensive care unit, use available electronic

monitors to track trends in vital signs without awakening the patient each hour. Other staff members need to be aware of the plan of care so they can cluster activities at certain times to reduce the number of awakenings. In a nursing home, the focus of the plan involves better planning of rest periods around the activities of the other residents. Often, patients' roommates have very different schedules and this must be considered.

The nature of the sleep disturbance determines whether referrals are necessary to additional health care providers. For example, if a sleep problem is related to a situational crisis or an emotional problem, you may refer the patient to a psychiatric clinical nurse specialist or a clinical psychologist for counselling. When a patient has chronic insomnia, a referral to a sleep centre is beneficial. If the patient needs a referral for continued care in the community, you should offer information about the sleep problem to the home care nurse. The success of sleep therapy depends on an approach that fits both the patient's lifestyle and the nature of the sleep disorder.

❖ Implementation

Nursing interventions that are designed to improve the quality of a person's rest and sleep focus largely on health promotion. Patients need adequate sleep and rest to maintain active and productive lives. During times of illness, rest and sleep promotion are important for recovery. Nursing care provided in acute care, restorative care, or continuing care settings differs from nursing care in the home setting. The primary differences are in the environment and the nurse's ability to support normal rest and sleep habits. The patient's age also influences the types of therapies that are most effective. Box 40-13 provides principles for promoting sleep in older patients.

Health Promotion

You can help patients in community health and home settings to develop behaviours conducive to rest and relaxation. To develop good sleep habits at home, patients and their bed partners need to learn the techniques that promote sleep and the conditions that interfere with sleep (Milner & Belicki, 2010) (Box 40-14). Parents should also learn how to promote good sleep habits for their children. Patients benefit most from instructions that are formed on the basis of information about their homes and lifestyles, such as the types of activities that promote sleep for a shift worker or ways to make the home environment more conducive to sleep. Patients will be more likely to apply information that is useful and relevant to their needs.

Environmental Controls. All patients require a sleeping environment with a comfortable room temperature, proper ventilation, minimal noise, a comfortable bed, and proper lighting (Morin, 2011). Children and adults vary in their preferences for a comfortable room temperature. Instruct parents to position cribs away from open windows or drafts and to cover the infant with a light, warm blanket. Older adults often require extra blankets or covers.

Eliminate distracting noise so that the bedroom is as quiet as possible. In the home, the television, telephone, or the intermittent chiming of a clock can disrupt a patient's sleep. The family becomes an important part of the approach to reduce noise in the home, especially if the home is shared with several family members, all with different bedtime schedules. Remember, however, that some patients are accustomed to sleeping

* BOX 40-13 FOCUS ON OLDER ADULTS

Promoting Sleep

Sleep-Wake Pattern

- Maintain a regular bedtime and wake-up schedule, even on weekends or vacations (Lee-Chiong, Jr., 2008).
- Eliminate naps unless they are a routine part of the schedule.
- If naps are used, limit them to 20 minutes or less, twice a day and avoid napping in the late afternoon or early evening.
- Go to bed when sleepy.
- Use a warm bath and relaxation techniques (reading, music, meditation, guided visual imagery) to promote sleep (Lee-Chiong, Jr., 2008).
- If unable to sleep within 15 to 30 minutes, get out of bed.
- Avoid work-related activities prior to bedtime (Milner & Belicki, 2010).

Environment

- Sleep where you sleep best.
- Keep noise to a minimum; use soft music to mask noise if necessary.
- Use a night light and keep the path to the bathroom free of obstacles.
- Set the room temperature to your preference; use socks to promote warmth.
- For "clock watchers" remove the clock from the bedroom.
- Listen to relaxing music (Morin, 2011).

Medications

- Use sedatives and hypnotics as a last resort, and then only for the short term if absolutely necessary (Mendelson, 2011).
- Adjust medications being taken for other conditions, and assess for drug interactions that may cause insomnia or excessive daytime sleepiness (EDS).

Diet

- Limit the intake of alcohol, caffeine, and nicotine in the late afternoon and evening (Lee-Chiong, Jr., 2008; Milner & Belicki, 2010).
- Consume carbohydrates or milk as a light snack before bedtime (Milner & Belicki, 2010).
- Decrease the intake of fluids two to four hours before sleep.

Physiological and Illness Factors

- Elevate the head of the bed and provide extra pillows as preferred.
- Use analgesics 30 minutes before bed to ease aches and pains.
- Use therapeutics to control symptoms of chronic conditions as prescribed (Lavigne et al., 2011).

with familiar inside noises, such as the hum of a fan. Commercial products that play soothing sounds, such as recordings of ocean waves or rainfall, can help to create a soothing environment for sleep.

The bed and mattress need to provide support and comfortable firmness. Bed boards can be placed under mattresses to provide additional support. Sometimes extra pillows can help to position a person comfortably in bed. For some patients, the position of the bed in the room also makes a difference.

Patients vary in their preference for the amount of light they can tolerate in the bedroom. Infants and older adults sleep best

► BOX 40-14 Sleep Hygiene Habits

Objective

- Patient will follow proper sleep hygiene habits at home.

Teaching Strategies

- Instruct the patient to try to exercise daily, preferably in the morning or afternoon, and to avoid vigorous exercise within two hours of bedtime.
- Caution the patient against sleeping long hours during weekends or holidays to prevent disturbance of the normal sleep–wake cycle.
- Explain that the patient should not use the bedroom for intensive studying, snacking, TV watching, or other nonsleep activity, besides sex.
- Encourage the patient to try to avoid worrisome thinking when going to bed and to practise relaxation exercises.
- If the patient does not fall asleep within 30 minutes of going to bed, advise the patient to get out of bed and do some quiet activity until the patient feels sleepy enough to go back to bed.
- Advise the patient to limit consumption of caffeine and alcohol.
- Ask the patient to examine the sleeping environment. If noise or light is an issue, suggest the use of earplugs or eyeshades.
- Instruct the patient to avoid heavy meals for three hours before bedtime; the patient may have a light snack before bedtime.

Evaluation

- Ask the patient to complete a sleep–wake and activity diary for one week, and compare it with the previous week's diary.
- Ask the patient to periodically complete a visual analogue or sleep rating scale to record perceptions of quality of sleep.

in softly lit rooms. Light should not shine directly on their eyes. Small table lamps can be used to prevent total darkness. For older adults, proper lighting reduces the chance of confusion and prevents falls while walking to the bathroom. Heavy shades, drapes, or slatted blinds are helpful if streetlights shine through windows, or if patients nap during the day.

Promoting Bedtime Routines. Bedtime routines help to relax patients in preparation for sleep (Milner & Belicki, 2010). Individuals should go to bed when they feel fatigued or sleepy. Going to bed while fully awake and thinking about other things often leads to insomnia and interferes with the perception of the bed as a stimulus for sleep. Newborns and infants sleep through so much of the day that a specific routine is hardly necessary. However, quiet activities, such as holding them snugly in blankets, singing or talking softly, and gentle rocking, help infants to fall asleep.

Parents need to reinforce short, predictable routines associated with preparing for bedtime (Milner & Belicki, 2010). A bedtime routine that is used consistently (e.g., the same hour for bedtime, eating a snack, or pursuing a quiet activity) helps young children to avoid delaying sleep. Bedtime routines can include quiet activities such as reading stories, colouring, allowing children to sit in a parent's lap while listening to music, or listening to a prayer.

Adults need to avoid excessive mental stimulation just before bedtime. Reading a light novel, watching an enjoyable television program, or listening to music can help a person to relax. Relaxation exercises, such as slow, deep breathing for one or two minutes, can help to relieve tension and prepare the body for rest (see Chapter 35). Guided imagery and praying also promote sleep for some patients.

At home, discourage patients from trying to finish office work or to resolve family problems before bedtime. The bedroom is not a place to work, and patients need to always associate the bedroom with sleep. Working toward a consistent time for sleeping and waking helps most patients to gain a healthy sleep pattern and to strengthen the rhythm of their sleep–wake cycle.

Promoting Safety. For any patient prone to confusion or falls, safety is critical. A small night light can assist the patient in orienting to the room environment before going to the bathroom. Beds set lower to the floor reduce the chance of a person falling when first standing. Instruct patients to remove clutter and small rugs from the path used to walk from the bed to the bathroom. If a patient needs assistance in ambulating from a bed to the bathroom, place a small bell at the bedside to call family members. Sleepwalkers are unaware of their surroundings and are slow to react, which increases their risk of falls. Do not startle sleepwalkers but instead gently awaken them and lead them back to bed.

Infants' beds need to be safe. To reduce the chance of suffocation, do not place pillows, stuffed toys, or the ends of loose blankets in cribs. Loose-fitting plastic mattress covers are dangerous because infants can pull them over their face and suffocate. Parents should place infants on their back to prevent sudden infant death syndrome (SIDS) (National Sleep Foundation, 2009a).

Promoting Comfort. People fall asleep only after feeling comfortable and relaxed (Carpenito-Moyet, 2008). Minor irritants often keep patients awake. Soft cotton nightclothes keep infants or small children warm and comfortable. Instruct patients to wear loose-fitting nightwear. An extra blanket is sometimes all that is necessary to prevent a person from feeling chilled and thus being unable to fall asleep. Patients need to void before retiring so they are not kept awake by a full bladder.

Establishing Periods of Rest and Sleep. Encourage patients living at home to stay physically active during the day so that they will be more likely to sleep at night. Increasing daytime activity reduces the likelihood of having problems with falling asleep. In the home setting, nurses frequently care for patients with chronic debilitating disease. The nursing care plan includes having patients set aside afternoons for rest to promote optimal health. To provide uninterrupted rest periods, adjust patients' medication schedules, instruct patients to void before rest periods, and suggest unplugging the telephone.

Stress Reduction. The inability to sleep because of emotional stress can make a person feel irritable and tense. When patients feel emotionally upset, encourage them not to force sleep. Otherwise, insomnia can develop, and bedtime is soon associated with the inability to relax. Encourage a patient who has difficulty falling asleep to get up and pursue a relaxing activity, such as reading, rather than staying in bed and thinking about sleep.

Preschoolers have bedtime fears (e.g., fear of the dark or fear of strange noises) and frequently awaken during the night or have nightmares. When a child experiences a nightmare, the parent should enter the child's room immediately and talk to the child briefly about fears to provide a cooling-down period. One approach is to comfort children and leave them in their own beds so that their fears are not used as an excuse to delay bedtime. Keeping a light turned on in the room will also help some children. Cultural tradition causes families to approach sleep practices differently (Box 40-15).

* BOX 40-15 CULTURAL ASPECTS OF CARE

Practices and patterns of sleep and rest vary among cultures. Culture and biology influence the development of sleep problems in children. Sleep patterns, bedtime routines, sleep aids, and sleep arrangements are a component of the cultural practices related to the use of space and the perception of comfortable distances for interactions with others. Sleep experts traditionally recommend having infants and children sleep in their own beds. Co-sleeping (i.e., the practice of infants and children sleeping with their parents) is a culturally preferred habit and is common in nonindustrialized countries. Health care providers in Canada frequently discourage this practice because of safety issues. The Canadian culture promotes independence in childhood. Because co-sleeping does not promote this independence, health care workers discourage it. As a nurse, you need to be culturally sensitive when discussing co-sleeping practices with parents and developing sleeping plans for children.

Implications for Practice

- Complete a thorough sleep assessment of the child and the family.
- Discuss the risks of the child sleeping with the parents. During the discussion, remain culturally sensitive and respectful of the parents' views.
- Co-sleeping affects the infant's normal sleep pattern by decreasing slow-wave sleep and increasing the number of nighttime arousals.
- Co-sleeping has been linked to an increased risk of sudden infant death syndrome (SIDS) under certain conditions, such as parental smoking and alcohol or drug use.
- Instruct parents who practise co-sleeping to avoid using alcohol or drugs that impair arousal. Decreased arousal prevents the parents from awakening if the child experiences problems.
- Co-sleeping should occur only with parents and not with another adult or child.
- Encourage the parents who co-sleep to use light sleeping clothes, to keep the room temperature comfortable, and to not bundle the child tightly or in too many clothes.

Bedtime Snacks. Some individuals enjoy bedtime snacks, whereas others cannot sleep after eating. A dairy product snack, such as warm milk or cocoa, contains L-tryptophan and is often helpful in promoting sleep. A full meal before bedtime often causes gastrointestinal upset and can interfere with the ability to fall asleep.

Encourage patients to avoid drinking or ingesting caffeine before bedtime. Because coffee, tea, cola, and chocolate act as stimulants, they can cause a person to stay awake or to awaken throughout the night (National Sleep Foundation, 2009a). Infants require special measures to minimize their nighttime awakenings for feeding. Children commonly need a middle-of-the-night bottle or to breastfeed at night. Hockenberry and Wilson (2007) recommend offering the last feeding as late as possible. Instruct parents not to give infants bottles in bed.

Pharmacological Approaches. Melatonin is a major hormone of the circadian system and plays an important role in promoting sleep (Buysse, 2011). Melatonin is a popular nutritional supplement to aid sleep. The recommended dosage is 0.3 to 1 mg taken two hours before bedtime (National Sleep Foundation, 2009b). Older adults who have decreased levels

of melatonin find taking melatonin to be beneficial as a sleep aid (Lee-Chiong, Jr., 2008). Several other herbal products also assist in promoting sleep. Valerian is effective in mild insomnia. It effects the release of neurotransmitters and produces a very mild sedation (Buysse, 2011). Kava helps promote sleep in patients who have sleep problems related to anxiety but needs to be used cautiously because of its potential toxic effects on the liver (Morin, 2011). Chamomile, passion flower, lemon balm, and lavender are other herbal products that have mild sedative effects. Caution patients about the dosage and use of herbal compounds. Because some herbal compounds interact with prescribed medication, patients should avoid using these treatments together (Krystal, 2011) (see Chapter 34).

The use of nonprescription sleeping medications is not advisable. Patients need to learn the risks of such drugs. Although these drugs initially seem to be effective, over the long term, they can lead to further sleep disruption. Help patients to use behavioural and proper sleep hygiene habits to establish sleep patterns that do not require the use of drugs.

Acute Care

Patients in an acute care setting frequently have their normal rest and sleep routines disrupted, which makes them more susceptible to periods of sleep deprivation. Sleep has a restorative function, hence, in this setting, nursing interventions should focus on controlling factors in the environment that disrupt sleep, relieving physiological or psychological barriers to sleep, and providing uninterrupted rest and sleep periods for the patient. The nurse may accomplish this by organizing procedures to minimize the number of times the patient's sleep must be disrupted and by avoiding any unnecessary procedures during rest periods.

Environmental Controls. In a hospital setting, nurses can promote rest and sleep periods by reducing or eliminating environmental disturbances. When possible, the doors to patients' rooms should be closed. In semiprivate rooms, the curtains should be closed between patients. At night, the lights on a nursing unit should be dimmed. Noise levels can be reduced by conducting conversations and reports away from patient rooms and by keeping necessary conversations to a minimum, especially at night; reducing the volume of alarms, televisions, and other equipment; turning off bedside oxygen and other equipment not in use and, when possible, avoiding noisy procedures till daytime hours (Carpenito-Moyet, 2008). Patients' use of cellular telephones and laptop computers should be discouraged during rest periods, and their minimal use during the hospitalization period should be encouraged. Moreover, the nurse should limit visitors during rest periods.

Promoting Comfort. Compared with beds at home, hospital beds are often harder and of a different height, length, or width. Keeping beds clean and dry and in a comfortable position helps patients to relax. Use pillows for support (painful limbs, splinting of surgical incisions). Some patients who have painful illnesses require special comfort measures, such as the application of dry or moist heat, use of supportive dressings or splints, or proper positioning before retiring (Figure 40-6).

Establishing Periods of Rest and Sleep. In a hospital or long-term care setting, it is sometimes difficult to provide patients with the time needed to rest and sleep. However, you should plan your nursing care to avoid awakening patients for nonessential tasks. When possible, schedule assessments, treatments, procedures, and routines for times when patients

Figure 40-6 Positioning a patient for sleep.

are awake. For example, if a patient's physical condition has been stable, avoid awakening the patient to check vital signs. Allowing patients to determine the timing and methods of delivery of personal care measures will promote rest. Do not choose to give baths and routine hygiene measures during the night because that timing may be most convenient for the nursing staff. Draw blood samples at a time when the patient is awake. Unless maintaining a drug's therapeutic blood level is essential, give medications during waking hours. Work with the radiology department and other support services to schedule diagnostic studies and therapies at intervals that allow patients time for rest. Always try to provide the patient with two to three hours of uninterrupted sleep during the night (Cmiel et al., 2004). The nurse may accomplish this by organizing procedures to minimize the number of times the patient's sleep must be disrupted and by avoiding any unnecessary procedures during rest periods.

When the patient's condition demands more frequent monitoring, schedule activities to allow the patient to have extended rest periods. Plan activities to ensure both that health care personnel will avoid returning to the room every few minutes and that the patient will have up to an hour or more to rest quietly. For example, if a patient needs frequent dressing changes, is receiving intravenous therapy, and has drainage tubes from several sites, do not make a separate trip into the room to attend to each task. Instead use a single visit to change the dressing, regulate the intravenous system, and empty the drainage tubes. Become the patient's advocate for promoting optimal sleep by postponing or rescheduling visits by family, asking consultants to reschedule visits, or questioning the frequency of certain procedures.

Promoting Safety. Patients with obstructive sleep apnea are at risk for complications while in the hospital. Surgery and anaesthesia disrupt the patients' normal sleep patterns. Postoperatively, these patients reach deep levels of

REM sleep. This deep sleep causes muscle relaxation that can lead to obstructive sleep apnea (Cao et al., 2011). Patients with OSA who are given opioid analgesics after surgery have an increased risk of developing airway obstruction because these medications suppress the normal arousal mechanisms (Cao et al., 2011). Monitor the patient's airway, respiratory rate, depth, and breath sounds frequently after surgery.

Recommend lifestyle changes to patients with OSA, including sleep hygiene improvements, alcohol moderation, smoking cessation, and a weight-loss program (Atwood, Jr., et al., 2011). Teach the patient to prevent sleeping in the supine position by wearing a fanny pack or tight shirt with a tennis ball on the back or by elevating the head of the bed 30 to 45 degrees (Atwood, Jr., et al., 2011). One of the most effective therapies is use of a nasal continuous positive airway pressure (CPAP) device at night, which requires a patient to wear a mask over the nose. The mask delivers room air at a high pressure and the air pressure prevents airway collapse. The CPAP device is portable and is effective particularly for obstructive sleep apnea (Buchanan & Grunstein, 2011).

Another treatment option is the use of an oral appliance. These appliances advance the mandible or tongue to relieve pharyngeal obstruction (Cistulli et al., 2011). In cases of severe sleep apnea, the tonsils, uvula, or portions of the soft palate are surgically removed. Success with surgical procedures is variable.

Stress Reduction. Patients who are hospitalized for extensive diagnostic testing often have difficulty resting or sleeping because of uncertainty about their state of health. Giving patients control over their health care minimizes uncertainty and anxiety. Providing information about the purpose of procedures and routines, and answering questions, will give patients the peace of mind they need to rest or to fall asleep. During the night shift, take time to sit and talk with patients who are unable to sleep. You may be able to determine the factors preventing patients from sleeping. Back rubs also help patients relax more thoroughly. If a sedative is indicated, confer with the physician to ensure the lowest dosage is used initially. Discontinue a sedative as soon as possible to prevent a dependence that can seriously disrupt the normal sleep cycle. Be aware that the metabolism of drugs in older adults is slower, making them more vulnerable to the side effects of sedatives, hypnotics, anti-anxiety drugs, and analgesics.

Restorative or Continuing Care

Nursing interventions implemented in the acute care setting are also used in the restorative or continuing care environment. Important considerations include controlling the environment, especially the noise level; establishing periods of rest and sleep; and promoting comfort. Nursing interventions related to the control of barriers to sleep are also implemented in these settings. Helping a patient achieve restful sleep in this environment sometimes takes a period of time.

Promoting Comfort. Comfort measures promote sleep and improve patients' sense of well-being. Nurses can promote comfort by offering a patient a warm bath or shower before bedtime. Other personal hygiene measures are mouth care and toileting (e.g., offering the bedpan or urinal). Back massages, soft music, and relaxation exercises also promote comfort. Proper positioning of the patient in bed is also very important. Using pillows to support limbs and other dependent body parts maintains skin integrity, thereby maintaining comfort (Milner & Belicki, 2010) (see Chapter 41).

Controlling Physiological Disturbances. Controlling the symptoms of patients with physical illnesses can promote sleep. For example, placing patients with respiratory disorders in upright bed positions and offering additional pillows may assist with their breathing. Teaching patients with chronic respiratory disorders (e.g., chronic obstructive pulmonary disease) pursed-lip breathing will decrease their respiratory rate and also promote comfort and sleep. Humidified air, the use of supplemental oxygen, if appropriate, and other pharmacological therapies (i.e., bronchodilators) are also relevant considerations.

Patients with pain, nausea, and other recurrent symptoms may require nonpharmacological and pharmacological therapies to promote sleep (Milner & Belicki, 2010; Morin, 2011). Relaxation measures (e.g., music, guided imagery) are appropriate diversional therapies. Providing pain relief with analgesics is also appropriate. To promote comfort and sleep, collaborate with physicians and other health care personnel to determine the optimal plan for relief of patients' symptoms (Milner & Belicki, 2011).

Pharmacological Approaches. Numerous pharmacological agents, both prescription and over-the-counter, are used to manage insomnia. Conversely, polypharmacy to manage insomnia is associated with disrupted sleep patterns, including increased nocturnal awakening and decreased REM sleep and total sleep time. Therefore, central nervous system (CNS) stimulants, such as amphetamines, caffeine, nicotine, terbutaline, theophylline, and pemoline, need to be used sparingly and only under medical management (O'Malley et al., 2011). In addition, withdrawal from CNS depressants, such as alcohol, barbiturates, tricyclic antidepressants (amitriptyline, imipramine, and doxepin), and triazolam can cause insomnia. You will need to manage these medications carefully.

Medications that induce sleep are called **hypnotics**. **Sedatives** are medications that produce a calming or soothing effect (Mendelson, 2011). Hypnotics and sedatives can be used as sleep medications and will help, if used correctly. A patient who takes sleep medications needs to understand their proper use, their risks, and their possible side effects. Long-term use of anti-anxiety, sedative, or hypnotic agents, however, can disrupt sleep and lead to more serious problems.

One group of drugs considered to be relatively safe is the benzodiazepines. The benzodiazepines cause relaxation, anti-anxiety, and hypnotic effects by facilitating the action of neurons in the CNS that suppress responsiveness to stimulation, thereby decreasing the levels of arousal (Mendelson, 2011). Unlike sedatives and hypnotics, benzodiazepines do not cause general CNS depression, and they also have a lower potential for abuse. These drugs are frequently prescribed because anti-anxiety effects occur at safe, nontoxic doses. In the older adult, short-acting benzodiazepines, such as temazepam and triazolam, are preferred over long-acting agents (Mendelson, 2011).

Administer benzodiazepines cautiously with children younger than 12 years of age. These medications are contraindicated in infants younger than six months. Pregnant women need to avoid benzodiazepines because their use is associated with the risk of congenital anomalies. Nursing mothers do not receive these drugs because they are excreted in breast milk. Initial doses are small, and increments are added gradually, on the basis of patient response, for a limited period of time. Warn patients not to take more than the prescribed dose, especially if the medication seems to become less effective after the initial

use. If older patients who were continent, ambulatory, and alert suddenly become incontinent, confused, or demonstrate impaired mobility, the use of benzodiazepines needs to be considered as a possible cause. Regular use of any sleep medication often leads to drug tolerance. Rebound insomnia is a problem that can be experienced after stopping the medication (Lee-Chiong, Jr., 2008). Immediately administering a sleeping medication when a hospitalized patient complains of being unable to sleep will do the patient more harm than good. Consider alternative approaches to promote sleep. Routine monitoring of the patient's response to sleeping medications is also important.

❖Evaluation

The patient is an important source of information for evaluating outcomes related to sleep and rest. Each patient has a unique need for sleep and rest, and only the patient will know whether sleep problems have improved, and which interventions or therapies are most successful in promoting sleep (Figure 40-7). To evaluate the effectiveness of nursing interventions, make comparisons with baseline sleep assessment data.

Determine whether expected outcomes have been met. Use evaluative measures shortly after a therapy has been tried (e.g., by observing whether a patient falls asleep after noise has been reduced and the room has been darkened). Use other evaluative measures after a patient awakens from sleep (e.g., by

Figure 40-7 Critical thinking model for sleep evaluation.

asking a patient to describe the number of awakenings during the previous night). The patient and the patient's bed partner can usually provide accurate evaluative information. Over longer periods, use assessment tools, such as the visual analogue scale or the sleep rating scale, to determine whether sleep has progressively improved.

You also need to evaluate the level of understanding that patients and their family members have gained after receiving instruction in sleep habits. You can measure compliance with these practices during a home visit, when you are able to observe the environment. When expected outcomes are not met, revise the nursing measures or expected outcomes, on the basis of the patient's needs or preferences. When outcomes are not met, ask questions such as "Do you feel as though you slept better when you exercised?" or "Do you feel rested when you wake up?"

When nurses successfully develop good relationships with patients and when they have developed therapeutic plans of care, subtle behaviours often indicate the patients' levels of satisfaction. Note the absence of signs of sleep problems, such as lethargy, frequent yawning, or position changes. Ask the patient whether his or her sleep needs have been met. For example, ask the patient, "Are you feeling more rested?" or "Can you tell me if you feel we have done all we can to help improve your sleep?" If the patient's expectations have not been met, you will need to spend more time trying to understand the patient's needs and preferences. Working closely with the patient and the patient's bed partner will enable you to redefine the expectations that can be realistically met within the limits of the patient's condition and treatment.

✦ KEY CONCEPTS

- Sleep provides physiological and psychological restoration.
- The 24-hour sleep-wake cycle is a circadian rhythm that influences physiological function and behaviour.
- The control and regulation of sleep depends on a balance between regulators within the central nervous system.
- During a typical night's sleep, a person passes through four to five complete sleep cycles. Each sleep cycle contains four nonrapid eye movement (NREM) stages of sleep and a period of rapid eye movement (REM) sleep.
- The most common type of sleep disorder is insomnia.
- The sleep pattern is frequently disrupted by the hectic pace of a person's lifestyle, emotional and psychological stress, and alcohol ingestion.
- If a patient's sleep is adequate, assess the patient's usual bedtime, normal bedtime ritual, preferred environment for sleeping, and usual rising time.
- When a patient reports a sleep problem, conduct a complete sleep history. Diagnosing sleep problems depends on identifying the factors that impair sleep.
- When planning interventions to promote sleep, consider the characteristics of the patient's home environment and normal lifestyle.
- A regular bedtime routine of relaxing activities prepares a person physically and mentally for sleep.
- An environment with a darkened room, reduced noise, comfortable bed, and good ventilation promotes sleep.
- Important nursing interventions for promoting sleep in the hospitalized patient are controlling noise levels and establishing periods for uninterrupted sleep and rest.
- Control of pain or other disease symptoms is essential in promoting the ability to sleep.

- Long-term use of sleeping pills often leads to difficulty in initiating and maintaining sleep.

✦ CRITICAL THINKING EXERCISES

1. Andree returns to the health care clinic with her husband, David, for a follow-up visit. She tells you that since she started her sleep hygiene plan she feels more rested but is still having some problems sleeping because of her husband's loud snoring. In addition to Andree's report of David's snoring, you note that he is overweight. On the basis of Andree's report of David's snoring, what additional assessment data should you gather from David?
2. On the basis of David's reported symptoms, what problem do you suspect he might have?
3. What action do you take at this time?
4. Andree and David also tell you that they are concerned about their 15-year-old daughter. Her grades in school are getting worse, and she says she is always tired. What do you need to know about their daughter's sleep patterns?
5. What would you recommend to Andree and David about their daughter?

✦ REVIEW QUESTIONS

1. You are gathering a sleep history from a patient who is being evaluated for obstructive sleep apnea. What symptom is the patient most likely to report?
 1. Headache
 2. Early awakening
 3. Impaired reasoning
 4. Excessive daytime sleepiness
2. When preparing a plan of care to promote sleep for a hospitalized patient, which of the following priority nursing interventions would you incorporate?
 1. Ensure that the patient follows hospital routines.
 2. Avoid awakening the patient for nonessential tasks.
 3. Give prescribed sleeping medications at dinner.
 4. Turn the TV volume down for late-night programming.
3. Older adults are cautioned about the long-term use of sedatives and hypnotics because these medications are characterized by which of the following statements?
 1. They cause headaches and nausea.
 2. They are expensive and difficult to obtain.
 3. They cause severe depression and anxiety.
 4. They can lead to sleep disruption.
4. You are providing health teaching for a patient using herbal compounds, such as valerian, to aid sleep. Key information about the use of herbal compounds would include the following:
 1. It can cause urinary retention.
 2. It may cause diarrhea and anxiety.
 3. It may interfere with prescribed medications.
 4. It can lead to further sleep problems over time.
5. A patient reports having vivid dreams. Through your understanding of the sleep cycle, you recognize that vivid dreaming occurs during which sleep phase?
 1. REM sleep
 2. Stage 1 NREM sleep
 3. Stage 4 NREM sleep
 4. Transition period from NREM to REM sleep

6. You are providing instruction for a patient who is having difficulty falling asleep. You identify the need for further instruction when the patient says which of the following statements?
 1. I should avoid having drinks with caffeine before going to bed.
 2. If I can't get to sleep right away, I should get up and read a book.
 3. I should have an alcoholic drink before bedtime to help me relax.
 4. I should avoid exercising just before going to bed.
7. Which of the following interventions is appropriate to include in a care plan for improving sleep in the older adult?
 1. Decrease fluids 2 to 4 hours before sleep.
 2. Exercise in the evening to increase fatigue.
 3. Allow the patient to sleep as late as possible.
 4. Take a nap during the day to make up for lost sleep.
8. Which statement made by a mother being discharged to home with her newborn infant indicates a need for further teaching?
 1. I won't put the baby to bed with a bottle.
 2. For the first few weeks, we are putting the cradle in our room.
 3. My grandmother told me that babies sleep better on their stomachs.
 4. I know I will have to get up during the night to feed the baby when he wakes up.
9. You are developing a plan of care for a patient experiencing narcolepsy. Which of the following interventions is appropriate to include in the plan?
 1. Increase the amount of carbohydrates in the diet.
 2. Limit fluid intake 2 hours before bedtime.
 3. Preserve energy by limiting exercise to morning hours.
 4. Take one or two 20-minute naps during the day.
10. Which of the following nursing measures promotes sleep in school-aged children?
 1. Encourage evening exercise.
 2. Encourage television viewing.
 3. Ensure the room is dark and quiet.
 4. Encourage quiet activities before bedtime.

✦ RECOMMENDED WEB SITES

Canadian Lung Association: <http://www.lung.ca>

This Web site provides information on obstructive sleep apnea, including strategies to enhance living with OSA and treatment modalities such as continuous positive airway pressure devices. Sleep apnea in children is discussed with exploration of strategies to reduce the impact of sleep apnea, including optimal nutrition and the use of CPAP devices.

Canadian Sleep Society: <http://www.css.to>

This Web site provides a conduit for health care providers and researchers who are interested in sleep-related disorders with an emphasis on sleep research performed in Canada. The site also includes information for the public on sleep-related topics and links to other sleep-related organizations to enhance the understanding of sleep and its related disorders through public awareness.

Sleep Apnea: Public Health Agency of Canada: <http://www.phac-aspc.gc.ca/cd-mc/sleepapnea-apneesommeil/index-eng.php>

This Web site includes publications intended for health care providers and the general public related to sleep apnea and other sleep disorders. It also includes a link to "Fast Facts from the 2009 Canadian Community Health Survey—Sleep Apnea Rapid Response." This survey, conducted by Statistics Canada, estimated for the first time the prevalence of sleep apnea in the Canadian population.

National Sleep Foundation (US): <http://www.sleepfoundation.org>

This multilingual Web site, designed for both health care providers and the public, provides an exhaustive amount of information regarding a plethora of sleep-related topics; for example, restless leg syndrome, dementia, and menopause. The site includes sleep-related educational material and research reports such as the 2011 annual Sleep in America poll that explores the impact of communication technology on sleep.

Veterans Affairs Canada: <http://www.veterans.gc.ca>

Focusing on the affairs of veterans, this Web site provides links to services, benefits, publications, and fact sheets relevant to Canadian veterans. Additionally, the site explores many issues facing Canadian veterans, including the impact of post-traumatic stress disorder (PTSD) on sleep and provides strategies to help get a good night's sleep.

Pain Assessment and Management

Original chapter by Linda Cason, MSN, RN-BC, NE-BC, CNRN

Canadian content written by Judy Rashotte, RN, PhD, Jacqueline Ellis, RN, PhD, Denise Harrison, RN, RM, PhD, and Brenda Martelli, RN(EC), MEd

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Discuss common misconceptions about pain.
- Describe the physiology of pain.
- Identify components of the pain experience.
- Explain how the physiology of pain relates to selecting interventions for pain relief.
- Describe the components of pain assessment.
- Perform an assessment of a patient experiencing pain.
- Explain how cultural factors influence the pain experience.
- Describe the appropriate nursing diagnoses, outcomes, and interventions for a patient with pain.
- Describe guidelines for selecting and individualizing pain interventions.
- Explain the various pharmacological approaches to treating pain.
- Describe applications for the use of nonpharmacological pain interventions.
- Discuss nursing implications for administering analgesics.
- Identify barriers to effective pain management.
- Evaluate a patient's response to pain interventions.

Pain is a common reason people seek health care. Despite being a commonly occurring symptom, even experienced by premature infants, pain is not well understood and is inconsistently and inadequately addressed (Stevens et al., 2011). **Pain** is defined as “an unpleasant, subjective sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage” (International Association for the Study of Pain Subcommittee on Taxonomy [IASP], 1979, 2008). This definition recognizes the physical and psychological nature of the pain experience. Pain is a highly personal experience, which can be accurately described only by the individual experiencing it (Pasero & McCaffery, 2011). This concept has endured for more than 40 years, when McCaffery first defined pain as “whatever the experiencing person says it is, existing

whenever he says it does" (McCaffery et al., 2011, p. 21). In recent years, definitions of pain have evolved to include the notion that a person's inability to verbally communicate does not preclude the possibility that pain is present or negate the responsibility of health care providers to treat it (Herr et al., 2006).

Relief from pain is considered a basic human right (Canadian Pain Society [CPS], 2001). Yet, in Canada, acute pain in hospitalized infants (Johnston et al., 2011), children (Stinson et al., 2008), and adults (Roth et al., 2005) and chronic pain in children (Palmero, 2009), adults (Boulanger et al., 2007), and the elderly (Martin et al., 2005) continue to be poorly assessed and treated. Nurses are ethically responsible for assessing and alleviating pain through the use of appropriate, evidence-informed pain management and provision of comfort measures. Nurses are also legally and ethically obligated to advocate for change in the care plan when pain relief is inadequate (Registered Nurses' Association of Ontario [RNAO], 2007). Responsive, evidence-informed pain management not only lessens pain but also improves quality of life and promotes earlier mobilization and return to work, resulting in fewer hospital and clinic visits, shortened hospital stays, and reduced health care costs.

Scientific Knowledge Base

Pain is part of the human experience. In the past, pain was viewed simply as a symptom of an illness or condition. Now, pain is understood to be complex, and chronic pain is considered to be a disease in its own right (Brookoff, 2000).

Nature of Pain

Pain is much more than a physical sensation caused by a specific stimulus. An individual's perception of pain has important *affective* (emotional), cognitive, behavioural, and sensory components that are shaped by past experience, culture, and situational factors. The nature of the stimulus for pain can be physical, psychological, or a combination of both.

Physiology of Pain

Pain is often classified by its inferred pathophysiology: nociceptive (physiological) pain or neuropathic pain. Nociceptive pain involves the normal neural processing of noxious stimuli that occurs when free nerve endings are activated by tissue damage or inflammation, while neuropathic pain involves the abnormal processing of stimuli from the peripheral or central nervous system and is thought to serve no useful purpose (Pasero & Portenoy, 2011).

Nociception has four specific processes: transduction, transmission, perception, and modulation (Arnstein, 2010). Patients in pain cannot discriminate among these four processes. However, understanding them will help you to recognize factors that can cause pain, symptoms that accompany pain, and the rationale and actions of selected therapies.

The first process involved in nociception is **transduction**. When tissue is damaged by thermal stimuli (e.g., burn), mechanical stimuli (e.g., cut), or chemical stimuli (e.g., chemotherapy), the damaged cells release sensitizing and inflammatory substances such as prostaglandins, bradykinin, histamine, prostaglandins, serotonin, and substance P (Box 41-1). These substances then activate nociceptors, resulting in transduction, or the generation of an electrical impulse (Pasero & Portenoy, 2011).

► BOX 41-1

Neurophysiology of Pain: Neuroregulators

Neurotransmitters (Excitatory)

Substance P

Found in the pain neurons of the dorsal horn (excitatory peptide)
Needed to transmit pain impulses from the periphery to the higher brain centre
Causes vasodilation and edema

Serotonin

Released from the brain stem and dorsal horn to inhibit pain transmission

Prostaglandins

Generated from the breakdown of phospholipids in cell membranes
Believed to increase sensitivity to pain

Neuromodulators (Inhibitory)

Endorphins and Dynorphins

Function as the body's natural supply of morphine-like substances
Activated by stress and pain
Located within the brain, spinal cord, and gastrointestinal tract
Cause analgesia when they attach to opiate receptors in the brain
Present in higher levels in people who have less pain than others with a similar injury

Bradykinin

Released from plasma that leaks from surrounding blood vessels at the site of tissue injury
Binds to receptors on peripheral nerves, increasing pain stimuli
Binds to cells that cause the chain reaction—producing prostaglandins

In the second process, **transmission**, these pain-sensitizing substances surround the pain fibres in the extracellular fluid, creating the spread of the pain message via the afferent peripheral nerve fibres to the spinal cord. Within the dorsal horn of the spinal cord, a synaptic transmission from the *afferent* (sensory) peripheral nerve to the spinothalamic tract nerves occurs through a complex neurophysiological and neurochemical mechanism, resulting in the relay of the signal to various higher brain centres (Arnstein, 2010; Figure 41-1).

Two types of afferent peripheral nerve fibres conduct painful stimuli: the fast, myelinated A-delta fibres, and the very small, slow, unmyelinated C fibres. The A fibres send sharp, localized, and distinct sensations that focus the source of the pain and detect its intensity. The C fibres relay impulses that are poorly localized, burning, and persistent (Meyer et al., 2006). For example, after stepping on a nail, a person initially feels a sharp, localized pain, which is a result of A-fibre transmission. Within a few seconds, the pain becomes more diffuse and widespread, until the whole foot aches, as a result of C-fibre innervation.

Pain stimuli continue to travel through nerve fibres in the spinothalamic tracts that cross to the opposite side of the spinal cord. Pain impulses then travel up the spinal cord. Figure 41-2 shows the normal pain reception pathway. After the pain impulse ascends the spinal cord, information is quickly transmitted by the thalamus to higher centres in the brain. These centres include the reticular formation, limbic system, somatosensory cortex, and association cortex.

Figure 41-1 Substance P and other neurotransmitters are released from primary afferent fibres that terminate in the dorsal horn of the spinal cord. **Source:** Paice, J. A. (1991). *Unraveling the mystery of pain.* *Oncology Nursing Forum*, 18(5), 843.

Figure 41-2 Spinothalamic pathway that conducts pain stimuli to the brain.

Perception, the third nociceptive process, is the conscious awareness of pain. Once a pain stimulus reaches the cerebral cortex, the brain interprets the intensity, quality, and character of the pain, and information from past experiences. As well, psychological, social, spiritual, and cultural associations are used to process the perception of the pain (Arnstein, 2010). The somatosensory cortex identifies the location and intensity of the pain, and the association cortex determines how we feel about the pain. Certain cells within the limbic system are believed to control emotion, particularly anxiety. Thus, the limbic system may play an active role in processing the emotional reaction to pain and the memory of the pain experience (Shyu & Vogt, 2009). However, the human ability to experience and remember pain does not depend on *cognitive ability* (explicit memory). The experience of pain is remembered by even the youngest of infants, including those born prematurely (Grunau & Tu, 2007). Pain studies using animal models have shown that significant exposure to pain can permanently alter a developing organism's pain mechanism (Sternberg & Al-Chaer, 2007). This suggests that physiological and implicit forms of pain memory take place in the first days of life.

As a person becomes aware of pain, a complex reaction unfolds. Psychological and cognitive factors interact with neurophysiological factors in the perception of pain. Perception gives awareness and meaning to pain so that a person can then react. The reaction to pain is the physiological and behavioural responses that occur after pain is perceived.

Modulation of pain is the final nociceptive phase and refers to the increase or decrease in pain signal intensity that can occur before, during, and after pain is perceived (Arnstein, 2010, p. 42). For example, once the brain perceives the pain, inhibitory neurotransmitters are released (see Box 41-1); these include endogenous opioids (endorphins and enkephalins), serotonin, norepinephrine, and gamma aminobutyric acid, which work to hinder the transmission of pain and help produce an analgesic effect (Arnstein, 2010).

A protective reflex response may also occur with pain reception (Figure 41-3). A-delta fibres send sensory impulses to the spinal cord, where they synapse with spinal motor neurons. The motor impulses travel via a reflex arc along *efferent* (motor) nerve fibres back to a peripheral muscle near the site of stimulation, thus bypassing the brain. Contraction of the muscle leads to a protective withdrawal from the source of pain. For example, when a person touches a hot iron, a burning sensation is felt, but the hand also reflexively withdraws from the iron's surface. When superficial fibres in the skin are stimulated, a person moves away from the pain source. If internal tissues such as muscle or mucous membranes become stimulated, tightening and guarding of muscles occur. This reflex is usually absent below the injury in patients with spinal cord injuries. However, patients with spinal cord injuries can still experience pain above the level of injury (Widerström-Noga et al., 2009).

Gate-Control Theory of Pain. No specific pain centre exists in the nervous system. Melzack and Wall's gate-control theory (1965) was the first to suggest that in addition to the physical sensation, pain has emotional and cognitive dimensions and that pain impulses can be regulated or even blocked by gating mechanisms located along the central nervous system. The theory suggests that pain impulses pass through when a gate is open and that impulses are blocked when a gate is closed. Closing the gate is the basis for pain-relief interventions. Gating mechanisms can be found in substantia gelatinosa

Figure 41-3 Protective reflex to pain stimulus.

cells within the dorsal horn of the spinal cord, thalamus, and limbic system. Understanding what physiological, emotional, and cognitive processes can influence these gates will help guide your approach to pain management. For example, stress, exercise, and other factors increase the release of endorphins, raising an individual's **pain threshold**, or the minimal intensity of a stimulus that is perceived as painful (IASP, 2008). Knowing that the amount of modulating substances varies with each person will help you to understand why pain intensity varies among patients, even for comparable stimuli, and why individuals exhibit different responses to pain.

Physiological Responses. As pain impulses ascend the spinal cord toward the brain stem and thalamus, the autonomic nervous system (ANS) becomes stimulated as part of the stress response. Superficial pain and pain of low to moderate intensity elicit the fight-or-flight reaction of the general adaptation syndrome (see Chapter 29). Stimulation of the sympathetic branch of the ANS results in physiological responses (Table 41-1). If the pain is continuous, severe, or deep, typically involving the visceral organs (e.g., with a myocardial infarction or colic from gallbladder or renal stones), the parasympathetic nervous system goes into action. Sustained physiological responses to pain could cause serious harm to an individual, such as altered immune response (Rittner et al., 2008). Except in cases of severe traumatic pain, which may result in shock, most people reach a level of adaptation in which physical signs return to normal. Thus, patients in pain will *not* always show changes in their vital signs. You need to consider physiological responses, but should avoid using them as sole measures to infer pain.

Behavioural Responses. Once pain is experienced, a cycle of events begins that, if not treated, managed, or relieved, can significantly diminish the meaning and quality of a person's life. Pain, especially intense acute pain or chronic pain, is physically and emotionally exhausting and thus can interfere, short or long term, with the ability to function and engage with others. Anxiety is often present initially, while depression, irritability, and chronic fatigue often accompany persistent pain. These responses to pain help explain why pain management can be so challenging.

Pain threatens physical, psychological, social, and spiritual well-being. Some patients will endure severe pain without

► TABLE 41-1 Physiological Reactions to Pain

Response	Cause or Effect
Sympathetic Stimulation*	
Dilation of bronchial tubes and increased respiratory rate	Provides increased oxygen intake
Increased heart rate	Provides increased oxygen transport
Peripheral vasoconstriction (pallor, elevation in blood pressure)	Elevates blood pressure with shift of blood supply from periphery and viscera to skeletal muscles and brain
Increased blood glucose level	Provides additional energy
Diaphoresis	Controls body temperature during stress
Increased muscle tension	Prepares muscles for action
Dilation of pupils	Affords better vision
Decreased gastrointestinal motility (nausea, vomiting)	Frees energy for more immediate activity
Parasympathetic Stimulation†	
Pallor	Causes blood supply to shift away from periphery
Muscle tension	Results from fatigue
Decreased heart rate and blood pressure	Results from vagal stimulation
Rapid, irregular breathing	Causes body defences to fail under prolonged stress of pain
Weakness or exhaustion	Results from expenditure of physical energy

*Superficial pain and pain of low to moderate intensity.

†Severe or deep pain.

asking for assistance. Some may not report pain if they believe their pain may inconvenience others or signals a loss of self-control. To ensure optimal health outcomes, it is important to discuss the benefits of using effective pain-management strategies with the patient so that activities of daily living are not seriously compromised. Remember, how patients respond to,

and their tolerance for, pain may significantly influence your perception of their degree of discomfort (McCaffery et al., 2007). Patients deemed to have a low **pain tolerance**, which is the greatest level of pain an individual is prepared to endure in a given situation (IASP, 1979, 2008), may be perceived as complainers. Acknowledge your own views, and avoid making judgements about another's pain. Teach patients the importance of self-reporting. Consider the immediate context in which a patient is experiencing pain, as well as his or her past pain experiences. Base your pain assessment and pain care decision making on a variety of sources and observations, such as patient self-reporting, family feedback, the patient's behaviour and physiology, and internal and external environmental factors.

Examples of body movements, facial expressions, and vocalizations that may indicate pain are protecting the painful part, bracing, rocking, body stiffening, jaw clenching, grimacing, frowning, crying, moaning, or screaming. Affective responses may be withdrawal, stoicism, fear, anxiety, anger, or feelings of hopelessness. You will learn to recognize common behaviour patterns that reflect pain, but you will need to remain flexible in your conclusions. Lack of pain expression does not necessarily mean that a person has no pain. For example, premature and full-term infants sometimes do not cry, and they may exhibit few motor movements, especially after excessive and repeated exposure to pain (Stevens, McGrath, et al., 2007). Similarly, opioids can blunt the behavioural expression of pain by sedating the patient. Yet, the patient who is sedated or sleeping can still be in pain (Pasero & Portenoy, 2011).

Types of Pain

There are many ways to classify pain. For example, pain may be categorized by duration, such as acute and chronic pain, or pathology, such as cancer pain and noncancer pain (e.g., pain associated with arthritis, diabetic neuropathy, low back pain, and headache).

Acute Pain. Acute pain usually has an identifiable cause, either somatic, visceral, or nociceptive (Arnstein, 2010), and is of short duration (usually less than six months). Acute pain has a predictable ending (healing) and an identifiable cause, and eventually resolves with or without treatment after a damaged area heals. Evidence, however, suggests that unrelieved acute pain may have development- and age-related consequences. For instance, significant and repeated exposure to acute pain during epochs of rapid early infant brain development may alter an infant's pain response (Taddio & Katz, 2005). Untreated or poorly treated intraoperative and postoperative pain and stress can also increase infant mortality and morbidity (Fitzgerald & Walker, 2009) or result in the development of chronic postsurgical pain (Macrae, 2008).

No matter what the age, unrelieved acute pain can seriously threaten recovery, resulting in prolonged hospitalization, increased risk of complications from immobility (see Chapter 45), and delayed rehabilitation. Physical or psychological progress may be compromised as long as acute pain persists, because the patient's prime focus may be on pain relief. Although complete pain elimination may not be achievable, working with your patient and the health care team to reduce pain to an acceptable level is realistic. Your primary goals should be to prevent pain whenever possible, effectively manage pain, and provide pain relief that allows patients to participate in their recovery.

Chronic Pain. Chronic pain was formerly defined as pain that is present for at least six months, persists beyond the normal time of healing, and may not have an identifiable cause (Jovey et al., 2003). It is now recognized that key elements of chronic pain can be evident much earlier (American Pain Society [APS], 1999). Chronic pain can be intermittent (occurs in a pattern) or persistent (lasting more than 12 hours daily) (Canadian Pain Coalition, 2011), experienced at any point in life, including early childhood (Stinson et al., 2011), and lead to great personal suffering. Chronic pain may be noncancerous or cancerous. Chronic noncancer pain is usually not life-threatening. However, patients with chronic noncancer pain are often frustrated because they never know how they will feel from day to day and the pain may be unrelenting. The pain may stem from an injured area that healed long ago but continues to result in pain that is nonresponsive to treatment. Chronic noncancer pain may be experienced along with other symptoms such as sleep disturbances, depression, anxiety, and anger (Wasan et al., 2007). This type of pain may be a major cause of psychological and physical disability, leading to problems such as job loss, the inability to perform simple daily activities, sexual dysfunction, and social isolation from family and friends.

Despite the fact that Canadians are among largest opioid users per capita in the world—indicative of a growing misuse of opioids—undertreated chronic noncancer pain is a challenge faced by patients and health care providers (College of Physicians and Surgeons of Ontario, 2010; National Opioid Use Guideline Group [NOUGG], 2010a). Now, more than ever, health care providers may be reluctant to treat this type of pain with opioids. Often, patients with chronic noncancer pain who exhibit behaviours seen in addictive disease, such as increasing demands for larger doses of opioids, are mistakenly diagnosed with addiction (i.e., **pseudoaddiction**) (Pasero et al., 2011). In fact, they are actually seeking pain relief as a result of undertreated pain. To help break the cycle of poor pain management, inform patients about concerns raised when they seek help from multiple health care providers, and refer the patient to a pain team, or chronic pain clinic if possible. A new Canadian guideline by NOUGG (2010b) addresses these challenges with recommendations and tools for safe and responsible selection, prescription, titration, and monitoring of opioids.

The beliefs and coping strategies used by individuals with chronic pain may determine how they will function with and adjust to pain. Esteve and colleagues (2007) found that individuals who believed they could control their pain, avoided viewing their condition as a tragedy, and believed that they were not severely disabled appeared to function better than those who did not. You should emphasize to the patient that pain can be successfully managed, although not necessarily cured. Make use of a comprehensive approach that includes both nonpharmacological and pharmacological strategies. Help strengthen the individual's confidence in his or her ability to control the pain, and suggest referral for treatment of possible depression, if necessary. Keep yourself updated about the best examples of adaptive coping strategies, such as cognitive behaviour therapy, by conducting a search of health databases.

Cancer Pain. Pain in a patient with cancer may be acute, chronic, or both. The pain may also be nociceptive, neuropathic, or both. Cancer pain may be caused by tumour progression and its related pathological process, invasive procedures, toxicities of treatment, infection, and physical limitations. It

can be sensed at the actual site of the tumour or distant to the site, which is called *referred* pain. A new report of pain by a patient with existing pain needs to be investigated. Although the need for treatment of cancer pain has become increasingly evident, the issue of undertreatment continues (Caraceni et al., 2004). Many individuals with cancer pain live in community settings, and pain relief is often provided by their families. Research findings suggest that accessing community resources may be difficult for these families and that the stress of caring for a loved one with cancer pain can affect the health of family caregivers (Harrison et al., 2009). The importance of establishing an organized, systematic, and comprehensive approach to pain assessment and treatment, as well as communicating with and supporting patients' families, cannot be overemphasized; nurses have the potential to play pivotal roles in these endeavours.

Pain by Inferred Pathology Process. Identifying the cause of pain is one of the first steps in successfully managing pain. Nociceptive pain is subdivided into *somatic* (musculoskeletal) and *visceral* (internal organ) pain. Neuropathic pain arises from abnormal or damaged pain nerves (Table 41-2). Each of these pathological processes has distinct pain characteristics that are discussed under pain assessment.

Breakthrough Pain. Some patients experience occasional, transitory exacerbations of intense pain, called **breakthrough pain**, because the pain “breaks through” the regular pain medication that adequately controls the baseline pain. Research has shown that breakthrough pain is not routinely recognized, evaluated, and treated (Portenoy et al., 2006). When breakthrough pain is brief and precipitated by an activity-related action, such as movement, sneezing, or coughing, it is referred to as *incident pain* (Pasero, Quinn et al., 2011, p. 310). *Idiopathic pain*, another subtype of breakthrough pain, is not associated with an identifiable cause and has a longer duration than incident pain (p. 310).

Nursing Knowledge Base

In *Notes on Nursing: What It Is and What It Is Not*, Florence Nightingale (1859; 1969) stated that “pain . . . perpetuates and intensifies itself.” Thus, nurses have a long history of dealing with the effects of pain on patients. In this section, factors that influence pain are explored.

Knowledge, Attitudes, and Beliefs

There are many factors that influence clinicians' tendencies to doubt patients' reports of pain. It is important to acknowledge that the knowledge, attitudes, and preferences of health care providers, including your own, will influence pain care decision making. Numerous studies on how clinicians judge the pain of others have indicated that, when compared with patients' self-reports, health care providers tend to underestimate or, on occasion, overestimate the patients' pain (McCaffery et al., 2007; Prkachin et al., 2007). For example, it has been demonstrated that nurses tend to overestimate pain when patients report no pain and underestimate pain when patients report mild to intense pain (Heikkinen et al., 2005), or when they are told that patients might be faking pain to obtain opioids (Kappesser et al., 2006). Experienced clinicians who repeatedly inflicted pain on patients tended to rate the clinical practice situation as less painful than inexperienced clinicians (Cheng et al., 2007). Differences in pain ratings may also result from the type of tool used for pain assessment

► TABLE 41-2

Classification of Pain by Inferred Pathology: Two Major Types of Pain

I. Nociceptive pain: Normal processing of stimuli that damages normal tissues or has the potential to do so if prolonged; usually responsive to nonopioids, opioids, or both.	II. Neuropathic pain: Abnormal processing of sensory input by the peripheral or central nervous system; treatment usually includes adjuvant analgesics.
A. Somatic pain: Arises from bone, joint, muscle, skin, or connective tissue. It is usually aching or throbbing in quality and is well localized.	A. Centrally generated pain. 1. Deafferentation pain. Injury to either the peripheral or central nervous system. Examples: Phantom pain may reflect injury to the peripheral nervous system; burning pain below the level of a spinal cord lesion reflects injury to the central nervous system. 2. Sympathetically maintained pain. Associated with dysregulation of the autonomic nervous system. Examples: May include some of the pain associated with complex regional pain syndrome (type I, type II).
B. Visceral pain: Arises from visceral organs, such as the gastrointestinal tract and pancreas. This may be subdivided: 1. Tumour involvement of the organ capsule, which causes aching and fairly well-localized pain. 2. Obstruction of hollow viscus, which causes intermittent cramping and poorly localized pain.	B. Peripherally generated pain 1. Painful polyneuropathies. Pain is felt along the distribution of many peripheral nerves. Examples: Diabetic neuropathy, alcohol-nutritional neuropathy, and those associated with Guillain-Barré syndrome. 2. Painful mononeuropathies. Usually associated with a known peripheral nerve injury, and pain is felt at least partly along the distribution of the damaged nerve. Examples: Nerve root compression, nerve entrapment, trigeminal neuralgia.

► BOX 41-2

Common Biases and Misconceptions About Pain

The following statements are false:

- Drug abusers and alcoholics overreact to discomfort.
- Patients with minor illnesses have less pain than do those with severe physical alterations.
- Regular administration of analgesics will lead to drug addiction.
- The amount of tissue damage in an injury can accurately indicate pain intensity.
- Health care providers are the best authorities on the nature of a patient's pain.
- Psychogenic pain is not real.
- Chronic pain is psychological.
- Patients should expect to have pain during a hospital stay.
- Patients who cannot speak do not feel pain.

(Chambers et al., 2005). We are often unaware of the process of inferring pain in others, yet our judgements guide our actions. For example, a nurse's personal opinion about the patient's report of pain affects the titration of opioid doses (McCaffery et al., 2011).

Making assumptions about patients in pain may seriously limit your ability to offer pain relief. Too often, nurses allow misconceptions about pain (Box 41-2) to affect their willingness to intervene. Some even avoid acknowledging a patient's pain because of their own fear and denial. Nurses are entitled to their personal beliefs; however, they must accept the patient's report of pain and act according to professional guidelines, standards, position statements, policies and procedures, and evidence-informed research findings. View the experience of pain from the patient's perspective. Become an active, knowledgeable observer of a patient in pain. This will not only help you to be more objective, it will allow you to provide a more holistic and effective approach to your pain care decision making and actions. These expressions of professionalism will be meaningful to the individual and improve his or her pain outcomes. The patient makes the observation that pain is present, and you apply techniques and skills that ultimately give relief.

Factors Influencing Pain

Pain is complex and involves physiological, social, spiritual, psychological, and cultural influences. Each individual's pain experience is different. Consider all factors that affect the patient in pain.

Physiological Factors

Age. Age is an important variable that influences pain, particularly in infants and older adults. Developmental differences among these age groups influence how children and older adults perceive and react to pain. Young children have difficulty understanding the procedures that you perform that may cause pain. Cognitively, toddlers and preschoolers are often unable to recall explanations about pain, or they associate pain with experiences that can occur in various situations. They may also have difficulty expressing their pain or may use verbal descriptors that differ from those used by older individuals (Stanford et al., 2005). Consider adapting your approaches when assessing pain in a child (including what to ask and the behaviours to observe). Help prepare the child for a painful procedure. Ask the child and parents about the terms most often used by the child to describe the pain experience

* BOX 41-3

FOCUS ON OLDER ADULTS

- With aging, muscle mass decreases, body fat increases, and the percentage of body water decreases. This results in the potential for an increased concentration of water-soluble drugs, such as morphine. Also, the volume of distribution for fat-soluble drugs, such as fentanyl, increases (Pergolizzi et al., 2008).
- Older adults frequently eat poorly, resulting in low serum albumin levels. Many drugs are highly protein bound. In the presence of low serum albumin, more of the active form of a drug remains unbound, which increases the risk for side effects, toxic effects, or both (Lehne, 2010).
- Decline of hepatic and renal function is a natural occurrence with aging. This results in reduced metabolism and excretion of drugs. Hence, older adults often experience a greater peak effect and longer duration of analgesics (Pergolizzi et al., 2008).
- Age-related changes in the skin, such as thinning and loss of elasticity, could affect the absorption rate of topical analgesics. However, transdermal analgesics have been proven beneficial for elderly patients and are particularly suitable for those with impaired gastrointestinal function (Pergolizzi et al., 2008).
- Patient-controlled analgesia (PCA) and regional analgesia are not contraindicated in older adults, but frequent assessment of pain, the side effects of analgesics, and cognition are necessary to ensure the efficacy and safety of PCA.
- The loss of the efficiency of homeostatic mechanisms puts older adults at risk for falls or delirium after the administration of sedative drugs or regional anaesthesia (Aubrun, 2005).

and pain treatment, and then use those terms when communicating about pain with the child.

Older adults may be more sensitive to severe pain as a result of structural, biochemical, and functional changes (Pergolizzi et al., 2008). Many elderly patients suffer cognitive impairment, confusion, or memory loss, either from pathology or medication, which can be compounded by sight and hearing impairment. Mobility, activities of daily living (ADLs), social activities outside the home, and activity tolerance can all be reduced. Pain in an older adult requires aggressive assessment, diagnosis, and management (Box 41-3).

The ability of older patients to interpret pain can be complicated by the presence of multiple diseases with vague symptoms that affect similar parts of the body. You will need to undertake a detailed assessment when a patient has more than one source of pain (Herr, 2002a, 2002b). The manifestations of different diseases can cause atypical presentations of painful conditions. Different diseases can also cause similar symptoms. For example, chest pain does not always indicate a heart attack; it may be a symptom of arthritis of the spine or of an abdominal disorder. Not all older adults experience cognitive impairment. However, when older adults are confused, they may not be able to recall and explain details of pain experiences. Misconceptions about pain management in the very young and in older adults may seriously hamper effective pain management for these populations (Tables 41-3 and 41-4).

Fatigue. Fatigue heightens pain perception, intensifies pain, and decreases coping abilities. This is a common problem for patients with long-term illnesses or with fatigue as a result of treatment. If fatigue occurs along with sleeplessness, the

► TABLE 41-3 Pain in Infants

Misconception	Correction
Infants cannot feel pain or are less sensitive to pain because of an immature nervous system.	Neuronal pathways are in place during gestation; consequently pain response exists even in the very premature neonate. Preterm and full-term neonates may have a greater sensitivity to pain than older infants and children. This is because of the high density of cutaneous nerve fibres, and their developing, but still immature, ability to inhibit transmission of sensory nerve impulses.
Infants are incapable of expressing pain.	Although infants cannot verbalize pain, they respond with behavioural cues and physiological indicators that can be observed by others.
Infants must learn about pain from previous painful experiences.	Emotional processing and cognitive abilities are maturational in nature and can influence the expression of pain and the ability to cope with pain. However, pain is present with the first insult; it need not be learned from an earlier painful experience (Grunau & Tu, 2007).
Pain cannot be accurately assessed in infants.	Behavioural responses, primarily facial expressions, can be reliably and validly assessed. Specific facial expressions are acknowledged as the most specific indicator of pain in response to acute noxious stimuli (Stevens, Pillai Riddell, et al., 2007). Numerous pain-assessment tools incorporating behavioural, physiological, and contextual indicators are available and recommended for use as part of effective pain management (Stevens, Pillai Riddell, et al., 2007).
Because infants cannot demonstrate cognitive awareness, they are insensible and lack memory for pain.	Early and repeated exposure to noxious stimuli can affect the infant's future responses to painful events (Grunau & Tu, 2007).
Analgesics and anaesthetics cannot be safely given to infants and neonates because of their immature capacity to metabolize and eliminate drugs, as well as their sensitivity to opioid-induced respiratory depression.	Infants older than one month of age metabolize drugs in the same manner as older infants and children. Careful selection of the agent, dosage, administration route, and time; frequent monitoring for desired and undesired effects; and drug titration and weaning can minimize the adverse effects of opioids and nonopioids for pain management in neonates (Taddio, 2007).

Sources: Adapted from McCaffery, M., & Pasero, C. (1999). *Pain: Clinical manual* (2nd ed.). St Louis, MO: Mosby; and Twycross, A. (2009). Why managing pain in children matters. In A. Twycross, S. J. Dowden, and E. Bruce (Eds.), *Managing pain in children: A clinical guide* (p. 5). Oxford, UK: Wiley-Blackwell.

perception of pain may be even greater. Less pain is often experienced after a restful sleep than at the end of a long day.

Heredity. Recent research on animal models suggests that genetic information passed on by parents might increase or decrease sensitivity to pain. What was historically described as pain threshold or pain tolerance may, in fact, be determined by genetic makeup (LaCroix-Fralish & Mogil, 2009).

Neurological Function. A patient's neurological function can influence the pain experience. Any factor that interrupts or influences normal pain reception or perception affects the patient's awareness of and response to pain. For example, patients who have a spinal cord injury, peripheral neuropathy (as in the case of diabetes mellitus), or a neurological disease (e.g., multiple sclerosis) experience altered pain sensation. Certain pharmacological agents influence pain perception and response. **Analgesics** (medications that relieve pain), sedatives, and **anaesthetics** (medications that cause temporary loss of sensation) depress functions of the central nervous system. Because patients at risk for pain insensitivity could suffer injury, they require preventive nursing care that includes neurological assessment (see Chapter 31).

Social Factors

Attention. The degree to which a patient focuses on pain can influence pain perception. Increased attention has been associated with increased pain, whereas distraction has been associated with a diminished pain response (Uman et al., 2008). This is a concept that nurses use when applying pain-relief interventions such as relaxation and massage. By focusing a patient's attention and concentration on other stimuli, his or her awareness of pain declines.

Previous Experience. Prior painful experiences may shape how a patient responds to subsequent painful events. If a person has had frequent episodes of pain without relief or has had bouts of severe pain, anxiety or fear may recur. In contrast, if a person has had repeated experiences with the same type of pain but the pain has been successfully relieved, it becomes easier to interpret the pain sensation. As a result, the patient is better prepared to take actions to relieve the pain.

When patients have had no prior exposure to a particular pain-inducing event, they may be unprepared, and this may impair their coping abilities. For example, severe incisional pain is common after abdominal surgery. Unless patients know to expect pain, they may view their incisional pain as a serious complication. As a result, they may tense up and breathe shallowly. Inform patients of the type of pain that might be experienced and methods to reduce it.

Family and Social Support. People in pain often depend on family or friends for support, assistance, or protection. A loved one can help minimize loneliness and fear. An absence of support can make the pain experience more stressful. The presence of parents is especially important for children with pain. Explain to the parent that children typically want their parents with them during a pain event, but warn them that a parent's own anxiety and responses may influence how the child experiences and responds to pain (Chambers et al., 2002). Provide parents with information about the procedure, and involve them by explaining how they can use pain-related distraction strategies with their child during the painful procedure.

Spiritual Factors. Religion and spirituality help individuals become part of a community or feel connected with nature or the universe. In some traditions, pain is viewed as retribution from God, or an opportunity to demonstrate the

TABLE 41-4 Pain in Older Adults

Misconception

Pain is a natural outcome of growing old.

Pain perception, or sensitivity, decreases with age.

If the older patient does not report pain, he or she does not have pain.

If an older patient appears to be occupied, asleep, or otherwise distracted from pain, he or she does not have pain.

The potential side effects of opioids make them too dangerous to use to relieve pain in older adults.

Patients with Alzheimer's disease and other cognitive impairments do not feel pain, and their reports of pain are most likely invalid.

Correction

Older adults are at greater risk than younger adults for many painful conditions; however, in the absence of disease, pain is not a normal part of aging.

Some studies suggest that greater age brings a higher threshold for painful electrical, thermal, and mechanical stimuli to the skin, while others have reported that older patients have alterations in the sensorineural apparatus, thus diminishing the perception of pain (Delgado-Guay & Bruera, 2008).

Older patients commonly underreport pain. Reasons include expecting to have pain with increasing age; not wanting to alarm loved ones; being fearful of losing independence; not wanting to distract, anger, or bother caregivers; and believing that caregivers know that the older patient has pain and are doing all that can be done to relieve it. The absence of a report of pain does not mean the absence of pain.

Older patients often believe it is unacceptable to show pain and have learned to use a variety of ways to cope with it instead (e.g., many patients use distraction successfully for short periods of time). Sleeping may be a coping strategy or may indicate exhaustion, not pain relief. Assumptions about the presence or absence of pain cannot be made solely on the basis of a patient's behaviour.

Opioids may be used safely in older adults. Although the opioid-naïve older adult may be more sensitive to opioids, this does not justify withholding their use in pain management for this population. Potentially dangerous opioid-induced side effects can be prevented with slow titration; regular, frequent monitoring and assessment of the patient's response; and adjustment of dose and interval between doses when side effects are detected. If necessary, clinically significant respiratory depression can be reversed by an opioid antagonist drug.

No evidence exists that cognitively impaired older adults experience less pain or that their reports of pain are less valid than those of individuals with intact cognitive function. It is probable that patients with dementia or other deficits of cognition suffer significant unrelieved pain and discomfort. Assessment of pain in these patients is challenging, but possible. The best approach is to accept the patient's report of pain and treat the pain as it would be treated in an individual with intact cognitive function.

strength of character that will be rewarded after death. Prayer, hope, and seeking spiritual support, such as attendance at church, have been linked to less suffering associated with pain (Wachholtz et al., 2007). But severe or prolonged pain can permeate the very essence of the person, eroding what is important, often challenging established beliefs and values, which may result in poorer pain outcomes (Rippentrop et al., 2005). Similarly, for those who view humans as irreducible energy fields in continual interaction with universal sources of energy, pain may be intensified or lessened as a result of changes in energy patterns.

Spiritual assessment tools such as FICA (Faith, Belief, Meaning; Importance and Influence; Community; and Address/Action in Care) are available (Maxwell et al., 2005). Explore potential religious/spiritual coping strategies with your patients such as meaning-making, distraction, spiritual supports, and relaxation techniques. For example, suggest a visitation from the clergy for those based in religious traditions or support the choice of therapeutic touch, Reiki, and acupuncture as restorative modalities designed to improve energy-flow patterns. Providing interventions designed to holistically heal is essential for the best possible pain management.

Psychological Factors

Anxiety. The relationship between pain and anxiety is complicated. Anxiety is associated with many types of pain; however, the cause-and-effect relationship has not been established (McCaffery et al., 2011). Pain often causes anxiety, but it is not clear that anxiety increases the intensity of pain. However, pain-related anxiety can result in the avoidance of activities that a patient fears may cause pain. When anxiety goes unnoticed, it may be difficult to manage pain effectively. The management of anxiety through the use of nonpharmacological and pharmacological approaches is appropriate. However, anxiolytic medications should not be used as a substitute for analgesia.

Meaning of Pain. The meaning of pain affects the experience of pain and how one adapts to it. A person will perceive pain differently if it suggests a threat, loss, punishment, or challenge. For example, a woman in labour may perceive pain differently than a woman with a history of cancer who experiences new pain and fears recurrence.

Cultural Factors. Culture shapes individuals' responses, behaviours, and attitudes about pain, and how they react to and cope with pain. People learn what is expected and accepted by their culture. Based on your own cultural beliefs, as a nurse

you may also expect that others will or should respond to pain in a particular manner. However, by understanding that pain has different meanings for different cultures, you can design culturally sensitive care.

Some cultures are demonstrative about pain; others are introverted. Your knowledge of the level of a patient's assimilation into Canadian society may be helpful. For example, if several generations of an Asian patient's family have lived in Canada, the influence of the Asian culture may be limited. In contrast, a recent immigrant from another culture may have different beliefs from those of the larger Canadian population. Explore the impact of cultural differences on the patient's pain experience, and adjust the plan of care (Box 41-4). Work with

BOX 41-4 CULTURAL ASPECTS OF CARE

Culture affects behavioural responses to pain and treatment preferences. For example, the Chinese culture includes Confucianism, which maintains that pain is an essential element of life and is a trial or a sacrifice (Chen et al., 2008). Thus, a patient with this belief would rather endure pain and not report it to a clinician, although they may report it to a family member. Although it is important that you become culturally competent in order to understand the characteristics of a culture, this knowledge does not tell you what to expect of a particular patient (McCaffery et al., 2011). Therefore, we encourage you to be sensitive to the differences among all individuals by seeking information from each patient and family about their specific beliefs. Remember to be mindful of the fact that the more difference there is between you and your patient, the more difficult it is for you to assess and treat the patient.

Implications for Practice

- Emotional and cognitive responses to pain (overt, stoic) vary between and within cultures.
- Words used to express pain vary among cultures (hurt, ache, discomfort).
- Personal and social meanings of pain and past pain experiences affect pain perception.
- The meaning of pain may influence the perception of pain intensity.
- Health care providers' beliefs and expectations regarding pain expression influence the use of pain management strategies.
- Therapeutic goals of pain management are influenced by cultural beliefs.
- Be aware of perceived causal factors of pain (fate, lifestyle, punishment, witchcraft).
- Believe patients' reports about their perceived pain; do not act on your own beliefs about a patient's pain.
- Seek information about the cultural backgrounds of your patients through discussion with your patients and families and best published evidence.

the patient and family to facilitate communication about the assessment and management of pain. Find a culturally appropriate assessment tool, and communicate the use of that tool to other health care providers.

Critical Thinking

Critical thinking requires synthesizing knowledge, experience, patient information, critical thinking attitudes, and professional standards. Clinical judgements require that you anticipate the information you need, analyze the data, and make decisions about patient care. A patient's condition or situation is always changing; thus, it is essential during pain assessments to consider all critical elements that will enable you to make a nursing diagnosis.

Knowledge about pain physiology and factors that influence pain will help you to manage patients' pain effectively. With experience, you will become more skilled at assessing pain and choosing effective therapies. Successful pain management does not necessarily mean pain elimination, but rather the attainment of mutually agreed upon pain-relief goals that allow patients to manage their pain and maintain function and quality of life.

Nursing Process and Pain

The nursing process provides you with a systematic approach to understanding and treating a patient's pain. An important aspect of effective pain management is establishing a trusting relationship with the patient and family. Pain management extends beyond pain relief; it encompasses the patient's quality of life and ability to work and play productively, and to function normally within the family and society (Arnstein, 2010).

Your application of the nursing process can be optimized by framing it around readily available clinical pain guidelines, which are based on best evidence and are continuously updated (see the Recommended Web Sites suggestions at the end of this chapter).

◆ Assessment

Pain assessment is the basis of all pain management and pain is often referred to as the fifth vital sign. Monitor the patient's pain consistently along with temperature, pulse, respirations, and blood pressure, especially if the pain is not well controlled. Establishing a nursing diagnosis, deciding on appropriate interventions, and evaluating the patient's response to the interventions are contingent on a timely and accurate pain assessment (Figure 41-4). Effective and unbiased pain assessment is best achieved if you use a validated pain assessment tool appropriate to the patient (McCaffery et al., 2011; RNAO, 2007).

Factors to consider when choosing an assessment tool include the age and developmental stage of the patient, patient condition, type of pain, culture, cognitive ability, preference, and ease of use for both the patient and the nurse (Arnstein, 2010; Wells et al., 2008). Specific tools are available that are appropriate for patients across the lifespan, from preterm neonates to the cognitively impaired elderly. Pain assessment can be as simple as obtaining a pain intensity score on a numerical scale of 0 to 10 or as complex as suggesting that a patient maintain a pain diary that includes pain intensity, pain location, pain descriptors, and the effects of pain on function and

Figure 41-4 Critical thinking model for pain and comfort assessment.

mood. The type of assessment will depend on the needs of the patient.

Establishing a pain goal with your patient will enable you to interpret the pain assessment data that you have collected. You might ask your patient, "What is an acceptable level of pain for you?" The patient might answer that a pain score of 2 (on a scale of 0 to 10, with 0 being no pain and 10 being the worst pain imaginable) is acceptable. You then focus on decreasing the pain to at least that level.

For patients with chronic or complex pain conditions, thorough assessment of pain should include affective, cognitive, and behavioural dimensions of the pain experience as well as a pain history (Institute for Clinical Systems Improvement, 2009). Your assessment of chronic noncancer complex pain should focus on the relationship between pain, function, quality of life, and treatment side effects because complete pain relief may not be possible. In the home setting, family members may assist with pain assessment. The ABCDE approach to pain ensures that you will remember the essential components of effective pain care (Box 41-5).

Failure of clinicians to assess a patient's pain, accept the findings, and treat the report of pain is a common cause of unrelieved pain and suffering (McCaffery et al., 2011). Use the

> BOX 41-5

Routine Clinical Approach to Pain Assessment and Management: ABCDE

- A: Ask about pain regularly. Assess pain systematically.
- B: Believe the patient and family in their report of pain and what relieves it.
- C: Choose pain control options appropriate for the patient, family, and setting.
- D: Deliver interventions in a timely, logical, and safe manner.
- E: Empower patients and their families. Enable them to control their treatment to the greatest extent possible.

right tools and methods to avoid errors, and choose the best pain interventions. Become aware of possible errors in pain assessment (Box 41-6).

Expression of Pain

A patient's self-report of pain is considered the "gold standard" and as such is the single most reliable indicator of the existence and intensity of pain (CPS, 2005; Jovey et al., 2003). Many patients fail to report or discuss pain; at the same time, many nurses believe that patients will report pain. If patients sense that you doubt their pain, they will share little or minimize their report of pain. It is important to establish a caring, therapeutic, trusting relationship that allows open communication about pain.

Patients unable to communicate their pain due to their age, medical condition, language requirements, or cognitive disability require special consideration throughout the pain assessment and treatment process. Choose a self-report or behavioural observation pain assessment tool that is appropriate for age, language, and condition of your patient. Assess and document pain and comfort behaviours before and after pain management interventions to gauge the effectiveness of treatments.

Cognitively impaired patients might require simple assessment approaches involving close observation of behaviour changes, especially with movement. Feldt (2000) designed the Checklist of Nonverbal Pain Indicators (CNPI), which focuses on behaviours for use with cognitively impaired older adults. The Pain Assessment in Advanced Dementia (PAINAD) provides a clinically relevant and easy-to-use pain assessment tool for individuals with advanced dementia (Warden et al., 2003) (Box 41-7).

Characteristics of Pain

Assessment of common pain characteristics will help you to understand the type and pattern of pain and aid in choosing interventions. When you assess pain and when you ask the patient for his or her self-report of pain, it is important to remember that using instruments to quantify the intensity and characteristics of pain depends on having a good fit between the needs of the patient and the attributes of the assessment tool. Developmental level, cognitive ability, language, and culture are a few factors to consider when assessing pain characteristics.

Onset and Duration. Ask questions to determine the onset, duration, and sequence of pain. When did the pain

► BOX 41-6

Possible Sources of Error When Assessing Pain

- Bias, which causes nurses to consistently overestimate or underestimate their patients' pain
- Unclear assessment questions, which lead to unreliable assessment data
- Use of pain assessment tools that have no established reliability or validity
- Expecting self-reports of pain from individuals who cannot rate their pain using a pain scale or who cannot provide a complete verbal account of their pain
- Not considering the pain context and the trajectory or change in an individual's expression of pain over time

begin? How long has it lasted? Does it occur at the same time each day? How often does it recur? Is there frequent breakthrough pain or prolonged pain recovery? Understanding the pattern and cycles of pain will enable you to intervene before the pain occurs or worsens.

Location. To assess location, ask the patient to point to painful areas using their own body as a guide or provide a body outline to record pain. When describing and recording pain location, use anatomical landmarks and descriptive terminology. The statement "The pain is localized in the upper right abdominal quadrant" is more specific than "The patient states that the pain is in the abdomen." Pain, classified by location, may be superficial or cutaneous, deep or visceral, referred, radiating, or neuropathic (Table 41-5). Examples of common pain medications are provided in Table 41-5 and explained elsewhere in this chapter. It is critical that you understand the type of pain the patient has, as pharmacological treatments will vary.

Intensity. Tools that assess pain intensity fall into two categories, self-report or behavioural observation. Examples of self-report scales include the verbal descriptor scale (VDS), the numerical rating scale (NRS), and the visual analogue scale (VAS) (Figure 41-5). When these scales are used to rate pain, a 10 cm or a 0 to 10 numerical baseline is recommended for consistent interpretation of the scores (von Baeyer & Hicks, 2000).

A VDS consists of a line with three- to five-word descriptors equally spaced along the line. The descriptors are ranked from "no pain" to "unbearable pain." Ask the patient to choose the descriptor that best reflects his or her current pain. An NRS has both numbers and descriptors to guide pain assessment. The scale anchors of 0 and 10 include verbal descriptors such as "no pain" and "most pain." The VAS consists of a straight line, representing a continuum of intensity, and has verbal descriptors at each end. Cartoon faces scales are self-report scales that can be used by children as young as 3 or 4 years of age and who do not understand numbers (Stanford et al., 2006). In addition, these scales are often well understood and acceptable to the cognitively impaired elderly (Taylor & Herr, 2003). The Wong-Baker FACES scale consists of six cartoon faces with verbal descriptors depicting increasing amounts of pain. The FACES scale was adapted to provide a culturally sensitive pain assessment tool in Inuktitut for use with Inuit children and adults and is called the Northern Pain Scale (Ellis et al., 2011) (Figure 41-6). The Faces Pain Scale-Revised (FPS-R) is another commonly used self-report scale and is composed of six semirealistic line drawings of pain faces (Bieri et al.,

* BOX 41-7

RESEARCH HIGHLIGHT**Sucrose for Reducing Pain in Infants****Research Focus**

Infants undergo painful procedures during their first year of life. Even healthy infants require blood sampling for newborn screening and receive injections for scheduled childhood immunization. Effective management of pain during these procedures is vital for the well-being of the developing infant. Canadian researchers have contributed substantially to the development of effective pain-management strategies for infants and have demonstrated analgesic effects of sweet-tasting solutions in diverse infant populations (Harrison, Bueno, et al., 2010; Stevens et al., 2010). Using evidence in your practice will help you provide the best care possible to patients of all ages.

**Research Abstract**

The purpose of the systematic review by Harrison and colleagues (Harrison, Stevens, et al., 2010) was to review all published studies of analgesic effects of sweet solutions in infants aged 1 to 12 months to determine if sweet solutions reduced pain during scheduled childhood immunization. Fourteen studies were included in the review. Results were that small volumes of sucrose and glucose, when given to infants to suck before their injections, reduced crying during and following the procedure. They recommended that health care providers use sucrose or glucose in their clinical practice when administering injections or performing other painful procedures on infants.

Evidence-Informed Practice

- Effective management of pain during painful procedures is important to the well-being of infants.
- Small volumes of sucrose or glucose significantly reduce pain during medical procedures in infants up to 1 year of age.
- Sweet solutions need to be given in small doses before and throughout the procedure.
- Use other pain-management strategies in addition to sweet solutions, such as offering the infant a pacifier if this is a normal part of their care.
- Support mothers to help their infants during immunization. For example, support mothers to breastfeed during immunization and to hold their infants securely.

1990; McCaffery et al., 2011) (Figure 41-7). Faces pain rating scales are easy for patients to use, easy for the nurse to score, and acceptable to both adults and children. Many of these tools have been translated into different languages and may be duplicated for use in your clinical practice (see Chapter 3 in Pasero & McCaffery, 2011).

If your patient cannot provide a pain intensity rating, choose a behavioural observation tool. These tools prompt you to observe your patient and score typical pain behaviours that sum to a pain intensity score. The Neonatal Infant Pain Scale

► TABLE 41-5 Classification of Pain by Location

Location	Characteristics	Examples of Causes	Examples of Common Medications
Superficial or Cutaneous Pain resulting from stimulation of skin	Pain is localized and of short duration. It is usually a sharp sensation.	Needle stick; small cut or laceration	Topical analgesics and anaesthetics (e.g., EMLA patch for children older than one year of age, Lidoderm patch for cutaneous neuropathic pain in adults)
Deep or Visceral Pain resulting from stimulation of internal organs	Pain is diffuse and may radiate in several directions. Duration varies, but it usually lasts longer than superficial pain. Pain may be sharp, dull, or unique to organ involved.	Crushing sensation (e.g., angina pectoris); burning sensation (e.g., gastric ulcer)	Demerol, morphine
Referred Common phenomenon in visceral pain because many organs themselves have no pain receptors; entrance of sensory neurons from affected organ into same spinal cord segment as neurons from areas where pain is felt; perception of pain is in unaffected areas	Pain is felt in a part of the body separate from the source of pain, and may assume any characteristic.	Myocardial infarction, which may cause referred pain to jaw, left arm, and left shoulder; kidney stones, which may refer pain to groin	Opioids (morphine) for acute MI by physician
Radiating Sensation of pain extending from initial site of injury to another body part	Pain feels as though it travels down or along the body part. It may be intermittent or constant.	Low-back pain from ruptured intravertebral disc, accompanied by pain radiating down leg from sciatic nerve irritation	Temporary treatment with one-time epidural injection of a steroid; injections of anaesthetics (e.g., xylocaine or bupivacaine)
Neuropathic Arises from abnormal or damaged pain nerves as a result of prior injury or disease; certain nerves may continue to send pain messages to brain even though no ongoing tissue damage is present (see Table 41-2)	Pain is usually described as burning, shooting, numbing, or electric-like.	Consequence of disease or prior injury to either the peripheral or central nervous system Complex regional pain syndrome, type I, type II, stroke, spinal cord injury, multiple sclerosis; diabetic neuropathy, alcohol-nutritional neuropathy, and those associated with Guillain-Barré syndrome; nerve root compression, nerve entrapment, trigeminal neuralgia; post-thoracotomy, herniorrhaphy, mastectomy; herpes zoster	Opioids, tricyclic antidepressants (e.g., nortriptyline), anticonvulsants (e.g. gabapentin), lidocaine patch

"Neuropathic" section based on Charlton, E. J. (Ed.). (2005). *Neuropathic pain. Core curriculum for professional education in pain* (pp. 1–8). Seattle, WA: IASP Press.

(NIPS) (Lawrence et al., 1993) and the Premature Infant Pain Profile (Stevens et al., 1996) specifically focus on the pain behaviours of premature and term babies. With the FLACC Postoperative Pain Tool, five categories of behaviour are scored: facial expression (F), leg movement (L), activity (A), cry (C), and consolability (C) (Manworren & Hynan, 2003; Merkel et al., 1997).

A pain scale should be easy for the patient to use and easy for the nurse to score and record in the patient's chart. You should use the same scale for the same patient consistently. Use a pain scale before and after an intervention to gauge the effectiveness of the intervention. A rating of 5 or more on a 0 to 10 scale requires immediate attention. However, a pain intensity score is only one component of best practice pain

care. Box 41-8 describes one nurse's effective solutions in caring for a young patient with burn injuries.

Quality. Another subjective characteristic of pain is its quality, and the descriptors that patients use will vary according to their habits, culture, age, and preference. For example,

some patients may use "hurt" and "ache," for mild pain but reserve the word "pain" for severe discomfort. The patient may describe the pain as crushing, throbbing, sharp, or dull. Certain pain descriptors are typically associated with certain conditions or injuries. For example, patients will often describe pain associated with a myocardial infarction as crushing or vise-like, and the pain of a surgical incision as dull, aching, and throbbing. Neuropathic pain is typically described as burning, shooting, or electric-like (Williams, 2006). The words that patients use to describe their pain will help to determine the type of pain they are experiencing and the treatment.

Pain Pattern. Various factors affect the pain pattern. It is important to assess for factors that precipitate or aggravate pain. Ask the patient to describe activities that cause or increase pain—for example, specific actions such as turning or bending. The low back pain and radiation down the leg associated with a ruptured intravertebral disc are usually aggravated by bending or lifting. Similarly, swallowing and talking typically aggravate the pain of pharyngitis. Asking the patient if the pain is worse at certain times of day, or if it is intermittent, constant, or a combination of both, will help you to plan effective interventions.

Relief Measures. Ask the patient what pain-relief measures he or she uses and which measures are found to be most effective. Patients with chronic, complex pain often have a number of pharmacological and nonpharmacological measures that help relieve pain. Physical and cognitive modalities such as heat or cold, exercise, gentle stretching, massage, acupuncture, imagery, relaxation, distraction, or music are

BOX 41-8 NURSING STORY

I was responsible for caring for 12-year-old Robert, who had extensive burns to both of his legs. His treatment involved daily dressing changes. His family lived in a rural area and was unable to visit their child during his hospitalization.

In my plan of care, I focused on managing Robert's pain. Burn injuries are associated with an intense inflammatory response. The release of chemical mediators that sensitize the active nociceptors at the site of injury cause the wound to become hypersensitized to mechanical stimuli such as touch, rubbing, or wound debridement, as well as to chemical stimuli such as antiseptics or other topical applications. Separation from family, fear of pain, and anxiety increase a child's perception of pain, and pain associated with daily dressing changes can affect how a child handles future painful events. Robert was instructed how to use a numerical 0 to 10 VAS and how to keep a pain diary. The VAS was administered at least every four hours, as well as before and after dressing changes. Based on Robert's pain goal, we aimed for a VAS target of 2 as an indicator of good pain control. This VAS was suitable for assessing pain intensity, was developmentally appropriate, and enabled Robert to provide a self-report of his pain. The pain diary helped us to assess his daily pain in order to adjust pain treatment.

Robert received around-the-clock oral morphine and a titrated bolus of oral morphine to relieve procedural pain before dressing changes. He also received a bolus of lorazepam to reduce anxiety before dressing changes and chose to play an interactive video game during dressing changes. I found that explaining what Robert could anticipate, and giving him the job of helping to remove some of his bandages, increased his involvement and sense of control. I also found that combining pharmacological pain treatment with allowing Robert to play his favourite interactive video game helped to reduce his anxiety during dressing changes. Best evidence suggests that these regimens contribute to the safe and efficacious use of opioids and adjuvants in children with burns.

I continuously monitored the effectiveness and safety of Robert's pain medication in order to assess for oversedation and to prevent breakthrough pain. As part of each pain assessment, I monitored Robert's vital signs, oxygen saturations, and sedation levels with the Pasero Opioid-Induced Sedation Scale (POSS), a reliable and valid sedation scale. I also monitored his fluid intake and urine output to make sure he wasn't becoming dehydrated and to help reduce opioid-related constipation. I checked Robert's temperature, respiration, and blood pressure every four hours for any signs of infection. I listened to his concerns, arranged for a child-life specialist and the teacher to visit Robert, and spoke daily with his family over the phone to discuss his care and progress.

components of a tool kit of pain-relief measures (Henwood & Ellis, 2004). Patients will often know what works best for them, and they appreciate that you are willing to listen and to try their techniques. You should also identify practitioners whose services the patient has used for pain management (e.g., orthopedist, acupuncturist, chiropractor, massage therapist).

Contributing Symptoms. Symptoms such as depression, anxiety, fatigue, nausea, anorexia, sleep disruption, spiritual distress, or guilt may increase suffering and aggravate pain. Assess for pain-associated symptoms and evaluate their effects on the patient's pain perception and pain tolerance. Monitoring and treating these symptoms contributes to effective pain management and improved quality of life.

► BOX 41-9 Behavioural Indicators of Pain**Vocalizations**

Moaning
Crying
Gasping
Grunting

Facial Expressions

Grimacing
Clenched teeth
Wrinkled forehead
Tightly closed or widely opened eyes
Lip biting

Body Movement

Restlessness
Immobilization
Muscle tension
Increased hand and finger movements
Pacing activities
Rhythmic or rubbing motions
Protective movement of body parts

Social Interaction

Avoidance of conversation
Focused only on activities for pain relief
Avoidance of social contacts
Reduced attention span
Despondent—failure to interact purposefully and meaningfully with immediate environment

Effects of Pain. Pain is a physiological, psychological, and psychosocial stressor that negatively affects all aspects of your patient's life. Unrelieved acute pain prolongs hospital stay and delays healing. Poorly controlled procedural pain from needle sticks may lead to "needle phobia" that sets the stage for treatment refusal or delay. Chronic and complex pain can severely challenge your patient's ability to function in all domains (Henwood et al., 2011).

Behavioural Effects. When a patient has pain, assess verbalization, vocal response, facial and body movements, and social interaction. For patients who cannot provide a verbal report of pain (e.g., infants, patients who are unconscious, disoriented, confused, or aphasic, and patients who speak a foreign language), it is important to assess behaviours that are indicative of pain. Grimacing, moaning, crying, inability to settle and rest, poor appetite, and negative emotions such as anger, fear, and anxiety are cues that your patient may be experiencing pain (Box 41-9).

Some nonverbal expressions characterize sources of pain. A person with chest pain often grabs or holds the chest. A person with severe abdominal pain often assumes a fetal position. The nonverbal expression of pain may support or contradict other information about pain. If a woman reports that her labour pains are occurring more frequently and begins to massage her abdomen more frequently, her report is confirmed. If a patient complains of severe abdominal pain but grasps the chest, a more detailed assessment may be necessary. For some patients, vocalizations are culturally acceptable ways to communicate and do not necessarily indicate a higher severity of pain or reduced pain tolerance.

Premature and full-term infants in pain often display characteristic facial actions. The Neonatal Facial Coding System (NFCS) (Grunau & Craig, 1987) is a coding tool for assessing pain-related changes in facial actions, such as brow lowering, eyes squeezing shut, chin quivering, mouth stretching vertically or horizontally, and lip pursing. Some infants, especially extremely preterm infants, may not cry or move in response to a painful stimulus (Stevens, McGrath, et al., 2007). This lack of pain response may also occur in older children and adults. Pain may result in the patient attending to the discomfort and fighting it or to giving in to the discomfort and withdrawing socially.

Influence on Activities of Daily Living. Patients who have daily pain may not be able to carry out routine activities. Inactivity leads to physical deconditioning. The primary goal should be to improve patient function. Ask patients if pain interferes with their sleep, awakens them, or keeps them awake (see Chapter 40). Nonpharmacological or pharmacological pain-management interventions may be needed to aid sleep.

Depending on the location of the pain, the patient may have difficulty performing activities of daily living, including basic hygiene, dressing, and grooming activities. For example, patients with severe arthritis may experience pain when grasping eating utensils or lowering themselves to a toilet seat. Assess the patient's need for assistance with self-care activities, and collaborate with members of the health care team (e.g., occupational therapist). Also, consider the need for family members or friends to assist the patient with basic hygiene.

Pain can affect sexual activity. Fear of worsening pain, arousal, confidence, performance, difficulty finding a comfortable position, and relationship problems are frequently reported pain-related problems (Josefsson & Gard, 2010; Kwan & Roberts, 2005). Prolonged use of opioids for cancer pain may affect sexual function and libido, as can the use of some adjuvant analgesics such as antidepressants (Pasero, Polomano, et al., 2011). Gently explore with your patient pain-related sexual issues and determine his or her preference for information-only and/or individual or group discussion to address these concerns. It is important not to neglect sexual issues when discussing pain. Be cautious that you do not display prejudices in providing sex-stereotyped advice. Assist your patient in locating appropriate self-help material that addresses pain-related sexual functioning (e.g., Lauren Andrew Hebert's book and video entitled *Sex and Back Pain: Advice on Restoring Comfortable Sex Lost to Back Pain*).

Pain also affects the ability of the patient to work. The more physical activity required in a job, the greater the risk of discomfort when the pain is associated with musculoskeletal and certain visceral alterations. Pain may increase if the job is stressful. Inquire about the patient's work, and assess whether pain affects his or her ability to function in the job. Assess the daily chores of homemakers in the same manner. Also assess whether it is necessary for patients to stop activity occasionally because of pain, and then help patients select ways of minimizing or controlling the pain so that they are able to remain productive.

It is also important to include an assessment of the effect of pain on social activities. The pain may be so debilitating that the patient becomes too exhausted to socialize. Identify the patient's normal social activities, the extent to which they have been disrupted, and the patient's desire to participate. Grief over lost goals or unfilled desires may augment pain.

BOX 41-10 NURSING DIAGNOSTIC PROCESS

Assessment Activities	Defining Characteristics	Nursing Diagnosis
Have patient describe pain intensity.	Pain is constant; 5 out of 10	Chronic pain related to chronic physical disability
Assess onset and location of pain.	Present for seven months in lower lumbar area	
Observe patient behaviours.	Grimaces and grunts with movement, rubs flanks frequently; reduced movement	
Assess effect of pain on activities of daily living (ADLs).	Appetite poor; gets little sleep; difficulty dressing	
Review medical history.	Previous trauma; previous exposure to opioids	

Patient Expectations

Patients who seek health care assistance with pain as a major symptom may have experienced the pain for many hours or days. Hospitalized patients may expect and even accept some pain. Asking patients to describe an acceptable pain level is a first step in encouraging them to take control of their pain. Assessing previous pain experiences and effective home interventions provides a foundation on which you can build. Patients expect that nurses will believe their reports of pain and be prompt in meeting their comfort needs.

Nursing Diagnosis

Do not diagnose pain simply because you assume that a patient will have discomfort. You will make an accurate diagnosis only after you have performed a complete assessment. The development of an accurate nursing diagnosis of pain results from thorough data collection and analysis (Box 41-10). Careful assessment, which should include examination of the patient's history for recent procedures or preexisting painful conditions, will reveal the presence of or potential for pain.

The nursing diagnosis focuses on the nature of the pain so that the nurse can identify the best interventions for relieving pain and minimizing its effect on function. Accurate identification of related factors ensures that appropriate nursing interventions will be chosen. For example, *acute pain related to physical trauma* versus *acute pain related to natural low-risk childbirth processes* require very different nursing interventions, such as "monitoring of vital signs for possible shock" versus "controlled breathing techniques." Examples of other diagnoses that may be applicable to patients at risk for pain are the following:

- Anxiety
- Ineffective coping
- Fatigue
- Fear
- Hopelessness
- Impaired physical mobility
- Imbalanced nutrition: less than body requirements
- Acute pain
- Chronic pain
- Powerlessness
- Ineffective role performance
- Self-care deficit
- Chronic low self-esteem
- Situational low self-esteem
- Risk for situational low self-esteem
- Sexual dysfunction
- Disturbed sleep pattern
- Impaired social interaction
- Spiritual distress

❖ Planning

The care plan integrates key patient information, critical thinking elements (Figure 41-8), and professional standards, which

Figure 41-8 Critical thinking model for comfort planning.

provide the best evidence for selecting nursing interventions (Box 41-11). Professional standards of care regarding pain management are available as agency policies or through professional organizations such as the RNAO or the Canadian Pain Society and its affiliated special interest groups. See recommended Web sites at the end of this chapter.

A concept map helps with care planning. Patients in pain frequently have interrelated problems. As one problem worsens, others also change. The concept map shows how nursing diagnoses link to one another and to medical diagnoses. For example, when planning care for the patient with arthritis, the nurse notes the relationships between *acute pain*, *impaired physical mobility*, *self-care*, and *fatigue* (Figure 41-9). Understanding these relationships helps the nurse to develop a holistic and patient-centred care plan.

Goals and Outcomes

Pain management goals permit the patient to function to the best possible extent. Determine with the patient what the pain has prevented the patient from doing and decide on a realistic and acceptable level of pain that will allow a return of function. Success is determined through attainment of goals and positive outcomes. For example, if the goal is “the patient will achieve a satisfactory level of pain relief within 24 hours,” the following are possible outcomes:

- Reporting that pain is a 3 or less on a scale of 0 to 10, or does not interfere with ADL
- Identifying factors that intensify pain, and modifying behaviour accordingly
- Using pain-relief measures safely

Setting Priorities

When setting priorities in pain management, consider the type of pain the patient is experiencing and the effects pain has on various body functions. Discuss the selected interventions appropriate for the nature and effects of the pain with the patient. For example, if a patient has had acute pain but an analgesic has brought relief, focus your attention on how the pain is influencing activity, appetite, and sleep. In contrast, when a patient's pain continues to be severe, immediate pain relief is the obvious priority. Your priorities will change as the patient's pain experience changes. Plans should take into account expected occurrences of pain.

Collaborative Pain Care

A comprehensive plan includes a variety of resources for pain control, including nurse specialists, pharmacists, physiotherapists, occupational therapists, clergy, and child life specialists for pediatric patients. For example, an oncology advanced practice nurse knows the pharmacological and nonpharmacological interventions that work best for chronic cancer pain. Pharmacists are knowledgeable about the effects, interactions, and adverse effects of multiple drug regimes often required to treat pain. Physiotherapists can plan exercises that strengthen muscle groups and lessen pain in affected areas. Occupational therapists can devise splints to support painful body parts. Child life specialists can plan social and play activities that reflect the developmental needs of the child. The family should also be involved in the care plan because they may need to administer care in the home after discharge. If the pain management plan is not successful, you should discuss the need for a change in treatment plan with the physician. Consultation with pain experts may be necessary.

► BOX 41-11 NURSING CARE PLAN

Acute Pain

Assessment

Mrs. Mays was diagnosed with a cancerous tumour in her left lung eight months ago. After treatment, she was taking oral analgesics on a prn basis. She can no longer tolerate taking medications orally and is now hospitalized with uncontrollable chest pain and possible pneumonia. Her husband is with her. A PCA of morphine 0.5 mg on-demand dose with a 10-minute lockout is begun.

Assessment Activities

Ask Mrs. Mays what she did at home to control her pain.

Findings and Defining Characteristics

Her pain escalated from a 3 to a 10, so she doubled her medication and went to bed. This did not help.

Ask Mrs. Mays what her pain intensity is now.

On a scale of 0 to 10, she reports a 9.

Ask Mrs. Mays what her pain has prevented her from doing.

She responds that she is unable to complete her own hygiene activities or sleep well.

Observe Mrs. Mays's nonverbal behaviour.

She is restless and unfocused during the history-taking.

Ask Mrs. Mays her pain intensity goal (out of 10).

She says that a pain intensity of 5 out of 10 would help her function better now. A goal of 3 would be preferred.

Nursing Diagnosis: Acute pain related to a biological injuring agent (tumour).

Planning

Goals (Nursing Outcomes Classification)*

Pain Control

Patient will obtain an acceptable level of comfort as soon as possible.

Expected Outcomes

Patient will report pain at stated goal or below prior to discharge.

Husband will assist in restoring Mrs. Mays to a more comfortable state.

Husband will provide selected comfort measures to Mrs. Mays before bedtime.

Pain: Disruptive Effects

Patient will actively participate in ADLs.

Mrs. Mays will report sleeping for five to six hours without interruption from pain.

She will complete her own hygiene with minimal assistance.

She will walk the hallway with her husband every four hours for 15 minutes.

Medication Response

Mrs. Mays will not experience unmanageable opioid side effects.

Mrs. Mays will report having a normal bowel movement every other day or similar to her baseline routine.

*Outcome classification labels from Moorhead, S., Johnson, M., Maas, M. L., & Swanson, E. (Eds.). (2008). *Nursing outcomes classification (NOC)* (4th ed.). St Louis, MO: Mosby/Elsevier.

Interventions (Nursing Interventions Classification)[†]

Pain Management

Begin PCA at ordered dose. Explain to patient and spouse how to use the PCA. Emphasize the importance of only the patient pushing the button, not the husband.

Rationale

Patient is experiencing an acute episode of her cancer pain. Discouraging the husband from pushing the button will minimize potential oversedating effects of the opioid because patient must be awake to perceive the pain and push the button (Wuhrman et al., 2007).

Monitor IV PCA morphine use. Explain to patient and spouse the action of the medication, potential side effects, and the importance of reporting if the pain is not relieved.

Pain is easier to prevent than to treat. Provide patient and spouse with written instructions regarding the use of the PCA pump. Instruct the husband to inform staff of unrelieved pain or unmanageable side effects (Pasero, Quinn, et al., 2011).

Have patient select nonpharmacological interventions that have relieved pain in the past (e.g., distraction, music, simple relaxation therapy, or massage).

Personal control allows a patient to shape immediate circumstances through his or her own actions. Nonpharmacological interventions augment pharmacological strategies, but should not be used in place of analgesics (Pasero & McCaffery, 2011).

[†]Intervention classification labels from Bulechek, G. M., Butcher, H. K., & McCloskey Dochterman, J. (Eds.). (2008). *Nursing interventions classification (NIC)* (5th ed.). St Louis, MO: Mosby/Elsevier.

BOX 41-11 NURSING CARE PLAN—cont'd

Evaluation

Nursing Actions

Ask Mrs. Mays if she attained her pain-relief goal most of the time.

Observe Mrs. Mays's ability to perform ADLs, walk, and sleep.

Ask Mr. Mays if he was able to give his wife a back massage.

Ask Mrs. Mays the time and consistency of her last bowel movement.

Patient Response and Finding

She responds, "My pain usually runs around a 3, which is my goal, except when I start walking."

She is dressed for breakfast and is walking the hallway every four hours with her husband. The night nurse's notes indicate Mrs. Mays slept through the night.

He reported that she did not want a back rub but preferred to have her feet rubbed, which he was happy to do. "She said it made her feel more relaxed."

She has not had a bowel movement in three days (since starting the morphine PCA).

Achievement of Outcome

Mrs. Mays reports an acceptable level of comfort, which is a change from the level that indicated unacceptable pain. Instruct her to push her button before ambulating.

Ability to perform ADLs and sleep has improved. Continue to monitor.

Nonpharmacological intervention was successful, but the nursing care plan was updated.

Assess her abdomen for bowel sounds and distension. Inquire about passing flatus. As constipation is the most common opioid adverse effect, consult with her physician about starting a stool softener and mild peristaltic stimulant. It is recommended to start these agents as soon as possible (Pasero, Quinn, et al., 2011).

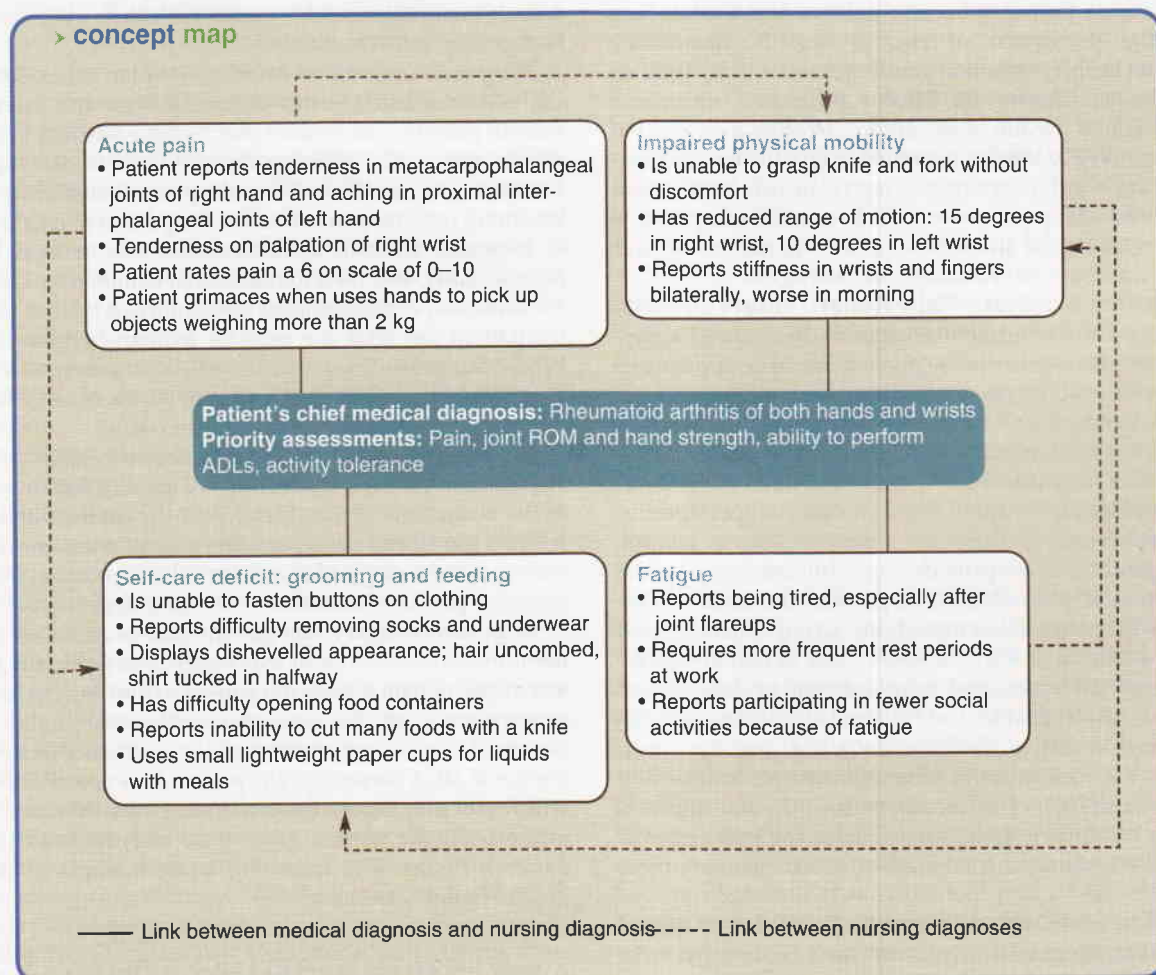

Figure 41-9 Concept map for patient with pain related to rheumatoid arthritis.

Implementation

The nature of the pain and how much it affects well-being determines the choice of interventions. Pain therapy requires an individualized approach, perhaps more so than any other patient problem. You, the patient, and the family must be partners in using pain-control measures. Administer and monitor pain treatments ordered by a physician, but consider using other complementary comfort measures. Patient remedies are often successful, especially when the patient has already had experience with pain. Generally, the least invasive and safest therapy should be tried first.

Health Promotion

The Ottawa Charter for Health Promotion (<https://www.who.int/healthpromotion/conferences/previous/ottawa/en/>) defines health promotion as the process of enabling individuals to gain control over and to improve their health and well-being (World Health Organization [WHO], 2008). Chronic pain and suffering diminish quality of life; thus, relieving pain and promoting self-control become important. Once pain is controlled to an acceptable level, provide patients and their families with education and information about pain so that they can participate in the pain care decision-making process. This will help reduce anxiety and increase a patient's sense of control. For example, patients who are in hospital for the first time may know that they require tests but do not understand them. As a result, they may become anxious and fearful. Fear increases the perception of painful stimuli. Remember, however, that health promotion goes beyond teaching. You can use the Ottawa Charter for Health Promotion document (Canadian Public Health Association, Health and Welfare Canada, and WHO, 1986)—a seminal and still useful document for today's public health practice (Hancock, 2007)—as a framework to develop your own skills in creating a supportive environment, using the strategies of enabling, mediating, and advocating for better pain-management services.

Nonpharmacological Pain-Relief Interventions.

Several nonpharmacological interventions do not need a physician's order but are initiated by nurses. Use these approaches in addition to, not in place of, pharmacological measures (Gruener & Lande, 2006). Nonpharmacological interventions include cognitive-behavioural and physical approaches.

The goals of cognitive-behavioural interventions, such as relaxation and guided imagery, are to change pain perceptions, alter pain behaviour, and provide a greater sense of control. Physical agents aim to provide comfort, correct physical dysfunction, alter physiological responses, and reduce fears associated with pain-related immobility. Complementary and alternative medicine (CAM) therapies, such as herbal supplements, energy therapies, and manipulation or body-based therapies, are also available. The National Center for Complementary and Alternative Medicine (NCCAM) and the Canadian Health Network, a health promotion service operated by the Public Health Agency of Canada, offer up-to-date information on their Web sites to assist you in answering your patients' questions, in a nonjudgemental manner, about the use of these methods.

Relaxation and Guided Imagery. Relaxation is mental and physical freedom from tension or stress. Relaxation techniques provide patients with self-control and can be used at any phase of health or illness. Relaxation techniques include meditation, yoga, Zen, guided imagery, and progressive relaxation exercises (see Chapter 34).

BOX 41-12 Body Positions for Relaxation

Sitting

Sit with entire back resting against back of chair.
Place feet flat on floor.
Keep legs separated.
Hang arms at the side or rest on chair arms.
Keep head aligned with spine.

Lying

Keep legs separated with toes pointed slightly outward.
Rest arms at sides without touching sides of body.
Keep head aligned with spine.
Use thin, small pillow under head.

For effective relaxation, patients must be in a state that will enable them to participate and cooperate. Relaxation is difficult to teach to patients in severe pain because they may not be able to focus and concentrate. The environment should be quiet and free of stimuli. The patient may sit in a comfortable chair or lie in bed (Box 41-12). A light sheet or blanket may help the patient feel more comfortable. Guided imagery and relaxation exercises may be done together or separately.

Progressive relaxation of the entire body takes about 15 minutes. The patient pays attention to the body, noting areas of tension. Warmth and relaxation replace tension in these areas. Some patients relax better with their eyes closed. Soft background music can help.

Progressive relaxation exercises involve controlled breathing exercises and a series of contractions and relaxation of muscle groups. The patient begins by breathing slowly and diaphragmatically, allowing the abdomen to rise slowly and the chest to expand fully. When the patient establishes a regular breathing pattern, you can coach the patient to locate any area of muscular tension, to think about how it feels, to tense muscles fully, and then to relax them completely. This creates the sensation of removing all discomfort and stress. Gradually the patient can relax the muscles without first tensing them. When full relaxation is achieved, pain perception may be lowered and anxiety about pain may decrease. Chapter 34 offers several relaxation exercise approaches.

If a patient becomes agitated or uncomfortable, it is best to stop the exercise. If the patient has difficulty relaxing any part of the body, slow the progression of the exercise and concentrate on the tensed body part. The patient must know that the exercise can be stopped at any time. With practice, the patient can soon perform relaxation exercises independently.

In **guided imagery**, the patient creates an image in his or her mind, concentrates on that image, and gradually becomes less aware of pain. Coach the patient in forming the image and concentrating on the sensory experience. Initially, ask the patient to think of a pleasant scene or experience that promotes the use of all of the senses. The patient may describe the image, which you may record for use during later exercises. Use the information the patient gives you, and do not change the patient's image. The following is an example of part of a guided imagery exercise:

Imagine you are lying on a cool bed of grass with the sounds of rushing water from a nearby stream. It's a balmy day. You turn to see a patch of blue wildflowers in bloom and can smell their fragrance.

Sit close enough to be heard, and speak in a calm, soft voice. While relaxing, the patient focuses on the image, and it will

become unnecessary for you to speak continuously. If the patient shows signs of agitation, restlessness, or discomfort, stop the exercise and try again when the patient is more at ease.

Distraction. The reticular activating system inhibits painful stimuli if a person receives sufficient or excessive sensory input. Boredom or isolation may cause patients to focus on their pain and thus perceive it more acutely. Pleasurable stimuli cause the release of endorphins that help a person ignore or become unaware of pain. Distraction, particularly effective for young children, directs attention to something else, thus reducing pain awareness and increasing tolerance. It works best for short, intense pain lasting a few minutes, such as a needle-stick or intravenous insertion. Examples are praying, describing photos or pictures aloud, listening to music, using therapeutic humour, and playing games, some involving the use of virtual reality technology (Dahlquist et al., 2009). Most distractions can be used in a hospital, home, or long-term care facility.

Music. Music can promote relaxation and decrease physiological pain, stress, and anxiety by diverting attention away from pain. Music can be chosen by either the patient or health care provider. Help create a relaxing setting so that music can be listened to uninterrupted. The use of earphones may assist with concentration and block out ambient noise. Although some benefits can be achieved with music therapy, the evidence is weak to moderate with regards to effects of music therapy on reduction of acute pain (Wells et al., 2008).

Biofeedback. Biofeedback is a behavioural therapy that involves giving individuals information about physiological responses (e.g., blood pressure or tension) and ways to exercise voluntary control over those responses (Rakel & Faass, 2006). It is used to produce deep relaxation and may be effective for regional pain syndrome management (Bruehl & Chung, 2006) and migraine headaches (Damen et al., 2006). In the treatment of headaches, electrodes are attached externally over each temple. The electrodes measure skin tension in microvolts. A polygraph machine visibly records the tension level for the patient to see. The patient learns to achieve optimal relaxation by lowering the actual level of tension experienced, using feedback from the polygraph. The therapy takes several weeks to learn. Chapter 34 describes the benefits and limitations of biofeedback.

Acupuncture. Acupuncture, traditionally embedded in naturalistic theories, may help reduce chronic and acute pain (Chou & Huffman, 2007) and, if properly performed, is a safe procedure. Acupuncture involves the insertion of acupuncture needles into specific “acupuncture points” (acupoints) on the patient’s body followed by the twisting of the needle up and down by hand. Evidence from numerous systematic reviews indicates that acupuncture is potentially effective for emesis developing after surgery or chemotherapy in adults, for nausea associated with pregnancy, and for relieving dental pain. During the last decades, our understanding of how acupuncture analgesia works has undergone considerable development. Acupuncture activates endogenous opioid mechanisms and may stimulate gene expression of neuropeptides (Zhao, 2008). The training and provision of acupuncture care in Canada is rapidly expanding. Chapter 34 describes the benefits and limitations of acupuncture.

Cutaneous Stimulation. Cutaneous stimulation, also referred to as touch healing (TH) therapies, is the stimulation of the skin to relieve pain. A massage, warm bath, ice bag, and transcutaneous electrical nerve stimulation (TENS) are simple ways to reduce pain perception. How cutaneous

Figure 41-10 Back massage pattern.

stimulation works is unclear. It has been suggested that TH therapies involve mechanisms of neural plasticity in somato-sensory maps, thus resulting in sensory reorganization (Kerr et al., 2007).

An advantage to cutaneous stimulation is that the measures can be used in the home, giving patients and families some control over pain symptoms and treatment. The proper use of cutaneous stimulation can reduce pain perception and help reduce muscle tension that might otherwise increase pain. Help the patient to get into a comfortable position, and explain the purpose of the therapy. Cutaneous stimulation should not be used directly on sensitive skin areas (e.g., burns, bruises, skin rashes, inflammation, underlying bone fractures).

Massage is a safe and effective way to reduce anxiety and minimize tension (Figure 41-10). Massage involves the manipulation of the soft tissues by either mechanical or physical means. Recent literature suggests that hand and foot massage can be an option, along with back or body massage. The recommended duration of massage is 5 to 20 minutes (Wells et al., 2008). Massages communicate caring and are easy for family members or health care providers to learn (Box 41-13).

Therapeutic touch (TT) and **Reiki** are classified as biofield, training-specific therapies, the medical use of subtle energy fields in and around the body for positive health effects. TT and Reiki involve the practitioner’s use of hands to help strengthen the body’s ability to heal. TT was developed in the 1970s by a nurse, Dr. Dolores Krieger (1979), and Reiki is an ancient practice believed to have originated thousands of years ago (Vitale, 2007). In recent years, nursing has been instrumental in exploring the benefits of energy work. Although there is still a lack of empirically based investigations to support these practices, nurses and others have been reporting clinical observations that the use of TT and Reiki has relaxation effects and stress management benefits, lessens pain, and promotes inner healing (Aghabati et al., 2010; Lee et al., 2008; Vitaler, 2007). Energy work has been endorsed as a valid modality for nursing intervention by a number of nursing groups across Canada, such as the Canadian Holistic Nursing Association and the Registered Nurses of Ontario’s Complementary Therapies Nurses’ Interest Group. You are encouraged to refer to Chapter 34 for additional information.

► BOX 41-13 Procedural Guideline

Massage

Delegation Considerations:

The nurse is responsible for assessing contraindications and patient response to massage. Administering a massage may be delegated to an unregulated care provider (UCP), providing that the patient is stable. Before delegation, you must do the following:

- Instruct the UCP about which body parts to massage.
- Instruct the UCP about the importance of not massaging reddened skin areas.
- Clarify the early signs of impaired skin integrity for select patients, and instruct the UCP to report changes in the patient's skin.

Equipment:

- Moisturizing lotion
- Bath towel or blanket

Procedure:

1. Assist patient to assume comfortable position.
2. Dim room lights, turn on soft music, or both, according to patient preference.
3. Perform hand hygiene. Warm lotion in hands or place container in warm water.
4. Adjust or remove patient's bed clothing.
5. Place small amount of lotion in your hands.
6. Massage each body part for at least 10 minutes.
 - A. *Back*: Begin a sacral area massage with a circular motion (see Figure 41-10), moving upward from buttocks to shoulders. Use a firm, smooth stroke over the scapula. Continue in one smooth stroke to upper arms and laterally along sides of back, down to iliac crests. Use long, gliding strokes along muscles of spine. Knead any muscles that feel tense or tight. Knead skin by gently grasping tissue between thumb and fingers. Knead upward along one side of the spine from buttocks to shoulders, around nape of neck. Knead or stroke downward toward sacrum. Repeat along other side of back.
 - B. *Neck*: Support neck at the hairline with one hand and massage upward with a gliding stroke. Knead muscles on one side. Switch hands to support neck, and knead other side. Stretch the neck slightly, with one hand at the top and the other at the bottom.
 - C. *Arms*: Use a gliding stroke to massage upwards from patient's wrist or forearm. With thumb and forefinger of both hands, knead muscles from forearm to shoulder. Continue kneading bicep, deltoid, and triceps muscles. Finish with gliding strokes from wrists to shoulder.
 - D. *Hands*: Slowly open patient's palm, and glide fingers over the palmar surface. Use thumbs to apply friction to palm and move thumbs in a circular motion. Stretch the palm outward. Massage each finger, using a corkscrew-like motion from the base of the finger to the tip. Gently knead each muscle in patient's fingers. Glide hands smoothly from fingertips to wrists. Repeat for other hand.
 - E. *Feet*: Gently massage top and bottom of each foot. Using gliding motion, massage from heel to toe. Gently massage the dorsal surface of the foot and each toe. Repeat for other foot.
7. Wipe excess lotion off patient's back, neck, or extremity. If necessary, assist patient to dress and resume a comfortable position.
8. Ask patient about level of comfort. Note any areas of muscle pain or tension.

Cold and heat applications relieve pain and promote healing. The choice of heat or cold varies with patients' condition and preference. Application of either method may require a physician's order (Wells et al., 2008). Moist heat can help relieve pain from a tension headache, and cold applications can reduce acute pain from inflamed joints. To avoid injury, check the temperature and avoid direct application of cold or heat to the skin. Patients at most risk for injury include those with spinal cord or other neurological injury, older adults, and confused patients.

Application of cold packs may be particularly effective for pain relief in certain conditions. Cold is particularly effective for dental pain and has been used effectively to relieve pain associated with coughing and breathing in postcardiac surgery (Chaillier et al., 2010). Cold applications are also effective before needle-stick procedures. Cold may be applied either near or distal to the pain site. The cold should be applied for 20 minutes to achieve maximum effect. Application near the actual site of pain tends to provide the most relief.

Heat application is another option. Heating pads or hot water bottles may be used. Commercial pillows that can be warmed in the microwave and that contour to the body can also be used. Although heat and cold applications are methods to consider when promoting comfort, few studies have been published regarding their impact on pain or functional qualities (Wells et al., 2008). Refer to Perry and Potter's (2010) textbook *Nursing Skills and Techniques* (7th edition) for further guidance on the performance of warm and cold therapy applications and the necessary safety precautions for use.

Another form of cutaneous stimulation, sometimes called counterstimulation, is **transcutaneous electrical nerve stimulation (TENS)**. TENS involves stimulation of the skin with a mild electrical current passed through external electrodes (Melzack & Wall, 2003). This therapy requires a physician's order. The TENS unit consists of a battery-powered transmitter, lead wires, and electrodes. The electrodes are placed directly over or near the pain site. Hair or skin preparations should be removed before attaching the electrodes. When a patient feels pain, the transmitter is turned on and a buzzing or tingling sensation is created. The patient may adjust the intensity and quality of skin stimulation. The tingling sensation can be applied until pain relief occurs. TENS may be effective for postsurgical pain control and reduction of pain caused by postoperative procedures. Consider consulting physiotherapy for TENS assessment and application.

Herbal Supplements. Herbal supplements have not been sufficiently studied to be recommended for pain relief; however, many patients self-medicate using supplements such as echinacea, ginseng, ginkgo biloba, and garlic supplements (Wirth et al., 2005). Some herbal products may interact with prescribed analgesics; in particular, ginkgo biloba may decrease the ability of blood to clot after surgery. Ask the patient to report all substances taken to relieve pain (Yoon & Schaffer, 2006) (see Chapter 34).

Reducing Pain Perception. One simple way to promote comfort is to remove or prevent painful stimuli (Box 41-14). Take steps to reduce patients' pain by paying attention to the way you perform procedures. This is especially important for patients who are immobilized or have difficulty in expressing themselves. Consider a patient's condition and the aspects of the procedure that are uncomfortable. Use techniques to avoid pain-producing situations. For example, in a patient with severe arthritic knee pain, know that extreme flexion of

► BOX 41-14

Controlling Painful Stimuli in the Patient's Environment

- Tighten and smooth wrinkled bed linen.
- Loosen constricting bandages (unless specifically applied as a pressure dressing).
- Change wet dressings and linens.
- Position patient in correct anatomical alignment.
- Check temperature of hot or cold applications, including bath water.
- Lift patient in bed—do not pull.
- Position patient correctly on bedpan.
- Avoid exposing skin or mucous membranes to irritants (e.g., urine, stool, wound drainage).
- Prevent urinary retention by keeping Foley catheters patent and free flowing.
- Prevent constipation with stool softeners, fluids, diet, and exercise.
- Reduce lighting and ambient sound.

the knee can cause pain. Before walking the patient to the bathroom, make sure that an elevated toilet seat is available. The patient can then be seated and can rise with minimal discomfort.

Acute Care

Acute Pain Management. Some patients have acute pain from invasive procedures (e.g., surgery or endoscopy), trauma, or cancer. The key to pain relief's success is the ongoing evaluation of interventions. Ask yourself the following questions: Is relief obtained? Do the medications cause any unacceptable side effects? It is the responsibility of the health care team to collaborate in order to find the combination of therapy that works best for the patient.

Pharmacological Pain-Relief Interventions. The ideal analgesic has yet to be developed, but many opioid and nonopioid pain-relieving medications are available. Most require a physician's order.

safety alert Your critical thinking and judgement in the selection and administration of analgesics helps to ensure safe and effective pain relief.

- Be cognizant of the pain diagnosis, the patient's physical characteristics (e.g., age), and severity of the illness; know that some analgesics will be contraindicated.
- Employ the 10 rights (person, drug, dose, route, time, documentation, reason, evaluation, patient education, and right to refuse) of medication administration.
- When dispensing opioids, be sure to check the dose and drug type, as the names of some common medications sound alike.
- Administer all analgesics using standardized guidelines.
- Evaluate analgesic effectiveness, and report and document any adverse effects.

Analgesics. Analgesics are a common and effective method of pain relief. Although analgesics can effectively relieve pain, nurses and physicians still tend to undertreat patients' pain.

Three types of analgesics exist: (1) nonsteroidal anti-inflammatory drugs (NSAIDs) and nonopioids, (2) **opioids**, and (3) coanalgesics, a variety of medications that enhance analgesics or have analgesic properties.

Acetaminophen (Tylenol) has no anti-inflammatory effects and works peripherally and centrally, but its action is unknown.

Its major adverse effect is hepatotoxicity. It is in a variety of over-the-counter (OTC) cold, flu, and allergy remedies. The maximum 24-hour dose for an adult is 4 g (the same dose limitation as aspirin) and is weight-dependent for infants and children. Acetaminophen does not affect platelet function and has minimal impact on the gastrointestinal tract (Arnstein, 2010). For postoperative, or severe, pain, it is often combined with opioids (e.g., Percocet, Vicodin, Lortab, and Ultracet) because it reduces the dose of opioid needed to achieve successful pain control. An overdose of acetaminophen can be fatal and is treated with acetylcysteine (Mucomyst).

Nonselective NSAIDs, such as aspirin and ibuprofen, provide relief for mild to moderate acute pain resulting from trauma or an inflammatory process (Arnstein, 2010). NSAIDs are believed to act by inhibiting the synthesis of prostaglandins (Pasero, Portenoy, & McCaffery, 2011) and thus the cellular responses to inflammation. Most NSAIDs act on peripheral nerve receptors to reduce transmission of pain stimuli. Unlike opioids, NSAIDs do not depress the central nervous system, nor do they interfere with bowel or bladder function (Pasero, Portenoy, & McCaffery, 2011). Chronic NSAID use in the older patient, however, is associated with more frequent adverse effects (e.g., gastrointestinal bleeding and renal insufficiency) and should be avoided (Arnstein, 2010). Taking NSAIDs with food reduces the likelihood of GI upset (Arnstein, 2010).

Nonselective NSAIDs have been found to be safe when taken for short periods of time. Celebrex is the only selective COX-2 inhibitor currently available; however, it should not be used in patients with a sulfa allergy. Some patients with asthma or an allergy to aspirin are also allergic to NSAIDs (Pasero, Portenoy, & McCaffery, 2011). Some NSAIDs are available OTC; advise patients to discuss using OTC NSAIDs for managing pain with their primary health provider (D'Arcy, 2006).

Codeine is a weak opioid used for moderate to severe pain. Although codeine has been widely prescribed for pain relief, recent advances in our understanding of the pharmacogenetics of codeine have forced a more rigorous investigation of its properties and adverse effects, particularly in the pediatric age group. Codeine is a prodrug. A prodrug is an opiod that must undergo chemical conversion to morphine to have an analgesic effect. Codeine's pharmacokinetics are variable and, in some patients, unpredictable.

Genetic variations exist that affect how the isoenzyme CYP2D6 converts codeine to morphine. Some patients may be ultrafast metabolizers, rapidly converting codeine to morphine. This places them at risk for oversedation and respiratory depression that could result in death. One case report details the death of a breastfed infant who died after receiving breast milk from a mother who had been prescribed codeine postpartum (Madadi et al., 2006). Two other young children died when they received codeine following a routine tonsillectomy procedure (MacDonald & MacLeod, 2010). Guidelines for infants, young children, and breastfeeding mothers should be modified until further research can be undertaken to better understand codeine and alternative pharmacological agents used (MacDonald & MacLeod). Alternative pharmacological agents should be used.

Opioid or opioid-like analgesics are generally prescribed for moderate to severe pain. These analgesics act by binding with opiate receptors to modify the perception of pain. An uncommon but potentially fatal adverse effect of opioids is oversedation and respiratory depression (Pasero, Quinn, et al., 2011). Respiratory depression caused by opioids can be

prevented using careful titration of opioids, close monitoring of sedation scores, and a thorough respiratory assessment including the depth, quality, and regularity of the respirations (Pasero, Quinn, et al., 2011).

If a patient experiences respiratory depression, an opioid antagonist such as naloxone can be administered. The dose must be titrated carefully and given as per physician order. Administering naloxone too quickly or administering too much can reverse the analgesic effect and produce severe pain that may be difficult to control. In addition, rapid administration can increase the sympathetic response and the patient may experience tachycardia, dysrhythmias, hypertension, pulmonary edema, and even cardiac arrest (Pasero, Quinn, et al., 2011). You need to carefully assess and reassess patients every 15 minutes for 2 hours after drug administration because of the risk of renarcotization and the return of respiratory depression. Naloxone is also used in smaller doses (1–2 mcg/kg IV) for the treatment of pruritus (Brislin & Rose, 2005).

Common adverse effects of opioids include nausea, vomiting, constipation, sedation, pruritus, and confusion. Less common effects include urinary retention, dry mouth, sweating, orthostatic hypotension, and seizures (Pasero, Quinn, et al., 2011). Most adverse effects are dose related; hence, a reduction in the opioid dose may treat the adverse effect or allow it to be more tolerable (Pasero, Quinn, et al., 2011).

Around-the-clock (ATC) dosing should be considered when pain exists for 12 out of 24 hours (Pasero, Quinn, et al., 2011). The benefits of ATC dosing include prevention in delay of timely medication administration and avoidance of the peaks and valleys of pain and analgesic blood levels associated with as-needed (prn) regimens.

As-needed dosing (prn) can be utilized to treat breakthrough pain; however, this method requires the patient's participation as he or she needs to request analgesia. Undertreatment of pain can occur if prn dosing is used for continuous pain. As-needed dosing is most useful when initiating opioid therapy to treat moderate to severe escalating pain or when pain is diminishing (Pasero, Quinn, et al., 2011).

The proper use of analgesics requires careful assessment and critical thinking in the application of pharmacological principles and logic. A patient's response to an analgesic is highly individualized. An NSAID can be as effective as or more effective than an opioid for some patients if the pain is caused by inflammation. An orally administered analgesic usually has a longer onset and duration of action than an injectable form. In addition, controlled- or extended-release opioid formulations (MS Contin, OxyContin, Kadian, Avinza, and methadone) are available for administration every 8 to 12 hours ATC. Physicians should not order these long-acting formulations on an as-needed basis.

It is essential that you know the comparative potencies of analgesics in both oral and injectable forms. In addition, know the route of administration most effective for a patient so that you can achieve controlled, sustained pain relief. If nurses on different shifts choose alternative routes for the same doses, the patient will not receive the same level of analgesia, and pain control will be poor. Equianalgesic charts are charts that convert one opioid to another (e.g., morphine to hydromorphone), or parenteral forms of opioids to oral forms (or vice versa). They are available on most nursing units or by contacting pharmacy team members. To see an example of an equianalgesic chart and pocket tool developed by the Massachusetts Pain Initiative in partnership with the

American Cancer Society, visit <http://masspaininitiative.org/files/PocketTool2008.pdf>.

Before administering opioids, it is important to consider the patient's situation, including current treatments, diseases and conditions, and organ (kidney and liver) function. Opioid doses often need adjusting according to patient circumstances. Situations requiring special considerations include opioid-naïve patients, breastfeeding mothers, patients on dialysis, those with neurological or respiratory conditions, and patients with recent abdominal surgery.

Adjuvants, or coanalgesics, are drugs that were originally developed to treat conditions other than pain but have been shown to have analgesic properties. Adjuvants, used for acute or chronic pain, can be employed as additional therapies or as a primary therapy for some specific painful conditions. Classes of drugs considered as adjuvant therapy include the following: anticonvulsants, such as gabapentin for neuropathic pain; antidepressants for neuropathic pain; corticosteroids; α_2 -adrenergic agonists, such as clonidine; cannabinoids; and topical analgesics (Pasero, Polomano, et al., 2011).

Patient-Controlled Analgesia. Patients benefit from having control over pain therapy. When patients depend on nurses for prn analgesia, an erratic cycle of alternating pain and analgesia often occurs. The patient feels pain and asks for medication, but the nurse must first assess the patient and then prepare the medication. Within an hour, analgesia finally occurs, but adequate pain relief may last only 30 to 60 minutes. The patient's discomfort then gradually escalates, and the cycle is repeated.

A drug delivery system called **patient-controlled analgesia (PCA)** is a safe method for pain management that allows patients to self-administer opioid doses (e.g., morphine, hydromorphone, fentanyl) on demand with minimal risk of overdose. PCA allows patients to "control" when they request analgesia and avoids the delay in waiting for pain relief. The goal is to maintain a constant plasma level of analgesic so that the problems of prn dosing are avoided. Systemic PCA typically pertains to IV administration, but PCA devices are also used to deliver pain medication via subcutaneous, epidural, intrathecal, and transdermal routes (Pasero, Quinn, et al., 2011). PCAs are portable computerized infusion pumps containing a chamber for a syringe (Figure 41-11) or bag that delivers a small, preset dose of medication. To receive a bolus dose, the patient activates a button attached to the PCA pump. To minimize overdoses, the system is designed with a preset "loc-out" interval, typically 5, 10, or 15 minutes. The system is designed to deliver a specified number of doses every hour. PCA can be ordered with bolus doses alone or bolus doses plus a continuous infusion (Pasero, Quinn, et al., 2011). PCA dosing is based on weight.

safety alert Remember to perform an independent double check with a qualified nurse colleague to ensure the medication and the pump settings (e.g., basal rate, bolus dose, loading dose, and lockout interval) are the same as ordered by the physician, and the same as indicated on the pain-management flow sheet and on the medication administration record.

PCA use is beneficial in many ways. The patient gains control over his or her pain, and pain relief does not depend on nurse availability. Patients can also access medication when they need it. This can decrease anxiety and lead to decreased

BOX 41-15

Preparation for Patient-Controlled Analgesia (PCA)

Objectives

- Patient will be able to explain the purpose of PCA in managing pain.
- Patient will use the PCA device correctly.
- Patient will achieve pain control.

Teaching Strategies

- Teach the use of PCA before it is needed so that patients can understand how to use it after awakening from anaesthesia or sedation. Reinforce as needed.
- Instruct patient on the purpose of PCA, emphasizing that the patient controls medication delivery.
- Explain that the lockout interval prevents the risk of overdose.
- Tell family members or friends that they should not operate the PCA device for the patient.
- Ask the patient to demonstrate use of the PCA delivery button.

Evaluation

- Ask patient to tell you the purpose of the PCA device.
- Observe the patient administering a dose.
- Evaluate the severity of the patient's pain 15 to 20 minutes after use of the PCA device.

medication use. Small doses of medications are delivered at short intervals, stabilizing serum drug concentrations for sustained pain relief.

Patients who do not favour PCA are those who feel they do not understand how to use the technology, while nurses view PCA as a disadvantage when it is ordered for patients with short-term memory loss or states of confusion (King & Walsh, 2007). Patient suitability, preparation, and teaching are, therefore, critical to the safe and effective use of PCA devices (Box 41-15). Teach patients how to use the technology and determine if they are physically able to locate and press the button to deliver the dose. Remind family members they must not press the button for patients, as this is deemed unauthorized administration of a dose by another person. The latter is referred to as PCA by proxy. Check to ensure your institution has established a policy that safeguards against PCA by proxy (Pasero, Quinn, et al., 2011).

Check the IV line and PCA device regularly to ensure proper functioning. Errors in pump programming can occur

that put the patient at risk for an overdose, resulting in oversedation and respiratory depression. In addition, opioid-naïve patients should be monitored carefully for both these adverse effects at the initiation of PCA therapy (Pasero, Quinn, et al., 2011).

The first mechanical device for oral medications, Medication on Demand (MOD), recently became available. This device allows patients access to their own oral prn medications, including opioids and other analgesics, anti-emetics, and anxiolytics, at the bedside. Research has shown this system is satisfying to patients and no reports of medication loss or inappropriate use (Rosati et al., 2007).

Local Analgesic Infusion Pump. Postoperatively, such as following cardiac (White et al., 2003) and orthopedic surgeries (Liu et al., 2006), an infusion of a local anaesthetic into the operative site may be effective for pain management and help to avoid systemic adverse effects of oral or intravenous analgesics. A catheter from the wound, placed during surgery, is connected to a pump containing a local anaesthetic, such as Marcaine. The infusion is usually left in place for 48 hours and may be set to either demand or continuous modes. Oral analgesics may still be needed by the patient, but the total dose is often reduced.

Topical Analgesics and Anaesthetics. Topical analgesics such as ELA-Max/LMX and EMLA (eutectic mixture of local anaesthetics) are available for both children and adults (Eidelman et al., 2005). Apply EMLA to the skin, via a disc or as thick cream, 30 to 60 minutes before minor procedures (e.g., IV start) or anaesthetic infiltration of soft tissue. Do not place EMLA around the eyes, on the tympanic membrane, or over large skin surfaces. The Lidoderm patch is a topical analgesic effective for cutaneous neuropathic pain in adults. Place three patches, cut to size, on and around the pain site using a 12-hour-on, 12-hour-off schedule to avoid lidocaine toxicity. Other topical analgesics include ketoprofen patches and capsaicin lotion (Pasero, Polomano, et al., 2011).

Sucrose. Oral sucrose is an effective strategy to reduce pain during procedures in infants (Harrison, Stevens, et al., 2010). Sweet taste is thought to trigger a release of endogenous opioids. Small volumes of sucrose are required, given in small doses throughout the duration of the painful procedure. Non-nutritive sucking such as the use of a pacifier may further assist with pain management. The efficacy of sucrose has been well demonstrated in infants undergoing painful procedures; however, further studies are required to determine efficacy in young children (Stevens et al., 2010).

Local and Regional Anaesthetics and Analgesics. **Local anaesthesia** is the infiltration of a local anaesthetic medication to induce loss of sensation to a localized body part. Physicians use local anaesthesia during brief surgical procedures, such as the removal of a skin lesion or suturing a wound. The local anaesthetic is topically applied on skin and mucous membranes, or injected subcutaneously or intradermally to anaesthetize a body part. The drugs produce temporary loss of sensation by inhibiting nerve conduction. Local anaesthetics can also block motor and autonomic functions, depending on the amount used and the location and depth of an injection. Smaller sensory nerve fibres are more sensitive to local anaesthetics than are large motor fibres. As a result, the patient loses sensation before losing motor function, and, conversely, motor activity returns before sensation.

Local anaesthetics can cause side effects, depending on their absorption into the circulation. Itching or burning of the skin or a localized rash is common after topical applications. Application to vascular mucous membranes increases the chance of systemic effects, such as a change in heart rate.

Regional anaesthesia is the injection of a local anaesthetic to block a group of sensory nerve fibres. Tissues are anaesthetized layer by layer, as the surgeon or anaesthesiologist introduces the agent into deeper structures of the body. Some types of regional anaesthesia are epidural anaesthesia, pudendal blocks, and spinal anaesthesia.

Whereas epidural anaesthesia induces temporary loss of sensation, **epidural analgesia** permits control or reduction of severe pain without the more serious sedative effects of parenteral or oral narcotics. Epidural analgesia is commonly used for the treatment of acute postoperative pain, labour and delivery pain, and chronic pain, especially when associated with cancer (Roman & Cabaj, 2005). Epidural catheters can be placed via the caudal, lumbar, or thoracic region (Brislin & Rose, 2005). However, intraspinal morphine can produce the same side effects of nausea, mental clouding, and sedation, because it is absorbed via the cerebrospinal fluid into the circulation of the epidural vascular plexus. Epidural analgesia can be short- or long-term, depending on the patient's condition and life expectancy. Short-term therapy is used for pain after intrathoracic, abdominal, and orthopedic surgery. Long-term therapy is particularly useful for intractable cancer pain (Raffaelli et al., 2006).

Epidural analgesia is administered into the spinal **epidural space** (Figure 41-12). The physician inserts a blunt-tip needle into the level of the vertebral interspace nearest to the area requiring analgesia. When the needle reaches the space, solutions may be freely injected and small catheters may be passed into it. Once a catheter is advanced into the epidural space and the needle is removed, the remainder of the catheter is secured with a dressing and taped along the back of the patient (Figure 41-13). If the catheter is only temporary, it is connected to tubing positioned along the spine and over the patient's shoulder. The end of the catheter can then be placed on the patient's chest for the nurse's access. Epidural analgesia may be anaesthesiology- or nurse-controlled, depending on agency policy. Patients may also be given control of the demand dose, which is known as patient-controlled epidural analgesia (PCEA). When PCEA is utilized, the basal rate is intended to meet the patient's analgesic requirements and the PCEA bolus doses are intended to control periods of breakthrough pain (Pasero, Quinn, et al., 2011). Infants may benefit from a single caudal block whereby a one-time dose of local anaesthetic is

Figure 41-12 Anatomical drawing of epidural space.

Figure 41-13 Epidural catheter taped in place.

administered to manage surgical pain, specifically with procedures below the level of the umbilicus (Verghese & Hannallah, 2005).

Nursing Implications. You can provide emotional support to patients receiving local or regional anaesthesia by explaining the procedure and warning patients that they will temporarily lose sensory function. Patients commonly fear paralysis because epidural and spinal injections come close to the spinal cord. To reassure the patient, explain that numbness, tingling, and coldness are common. Before a patient receives an analgesic, check for allergies and assess baseline vital signs to monitor systemic effects.

After administration of a local anaesthetic, protect the patient from injury until full sensory and motor function return. Patients are at risk for injuring the anaesthetized body

part without knowing it. For example, after an injection into a joint, warn the patient to avoid using the joint until function returns. For patients with topical anaesthesia, avoid applying heat or cold to numb areas. After spinal anaesthesia, instruct the patient to stay in bed until sensory and motor function return. Assist the patient during the first attempt at getting out of the bed. Ensure proper footwear is worn to prevent falls and to optimize stability.

When managing epidural infusions, connect the catheter to an infusion pump, a port, or a reservoir, or cap it off for bolus injections. To reduce the risk of accidental epidural injection of drugs intended for IV use, clearly label the catheter as an “epidural catheter.” Always administer continuous infusions through electronic infusion devices for proper control. Because of the catheter location, use surgical asepsis to prevent a serious and potentially fatal infection. Notify the physician immediately of any signs or symptoms of infection or pain at the insertion site. Thorough hygiene is necessary during nursing procedures to keep the catheter system clean and dry. Nursing implications for managing epidural analgesia are summarized in Table 41-6.

Supplemental doses of opioids or sedatives (hypnotics) are avoided because they have additive effects that can be detrimental to the central nervous system. Monitoring of

medication adverse effects differs, depending on whether infusions are intermittent or continuous. If opioids are to be administered, mu agonist opioids, such as morphine, fentanyl, and hydromorphone, are the most common choices (Pasero, Quinn, et al., 2011). Adverse reactions can be related to the opioid or the local anaesthetic agent. Refer to your specific institutional protocols for monitoring standards.

Instruct patients about the action of the medication, advantages and disadvantages of the epidural route of medication, and potential side effects, and request they notify a health provider if they develop any side effects. If the patient requires long-term epidural use, inform him or her that a permanent catheter may be tunnelled through the skin and exit at the patient’s side. Teach patients on long-term therapy how to safely administer infusions in the home with minimal ongoing intervention by the nurse.

Invasive Interventions for Pain Relief. When pain is severe, invasive interventions may give relief when more conservative treatment is neither tolerated nor effective. These interventions include intrathecal implantable pumps or injections, spinal cord stimulators, deep brain stimulation, neuroablative procedures (e.g., **chordotomy**, **dorsal rhizotomy**, **thalamotomy**), trigger point injections, radiofrequency ablation, cryoablation, intradiscal electrothermal (IDET) annuloplasty, vertebroplasty, intraspinal medications (e.g., opioids, steroids, local anaesthetics, alpha agonists), and others (Vanni & Rehm, 2010). It is not acceptable to tell a patient with severe unrelieved pain that “there is nothing more we can do for you.” Patients with pain unresponsive to medications need consultation with a pain expert or an interprofessional pain team.

Procedure Pain Management

The Thunder Project II (Puntillo, 2003) identified several procedures in critical care patients that cause pain:

- Turning
- Wound drain removal
- Tracheal suctioning
- Femoral catheter removal
- Placement of central line
- Changing of wound dressings

Premedicating patients before painful procedures may assist them to cooperate and may help to reduce the experience of pain. This is also true for patients who present in the emergency department with abdominal pain. The American Pain Society (2003) recommends medicating the patient in pain before conducting an extensive physical examination or diagnostic procedures.

Cancer Pain Management. Cancer pain may be chronic or acute or a combination. A number of key organizations across Canada, such as Cancer Care Ontario’s Cancer-Related Pain Management Guideline Panel (Green et al., 2010), the Canadian Pain Society (2005), and Cancer Care Nova Scotia (2005) have released evidence-informed clinical practice guidelines for the management of cancer pain. These guidelines are designed to treat cancer pain in a more comprehensive and aggressive manner and provide patients and families with options for pain relief. The choice of treatment may change as the patient’s condition and the characteristics of pain change. Effective pain management is best achieved when pharmacological and nonpharmacological pain interventions are used together and is part of an interprofessional collaborative team approach.

► TABLE 41-6

Nursing Care for Patients With Epidural Infusions

Goal	Actions
Prevent catheter displacement. Maintain catheter function.	Secure catheter (if not connected to implanted reservoir) carefully on skin. Check external dressing around catheter site for dampness or discharge. (Leak of cerebrospinal fluid may develop.) Use transparent dressing to secure catheter and to aid inspection. Inspect catheter for breaks.
Prevent infection.	Use strict aseptic technique when caring for catheter (see Chapter 32). Do not routinely change dressing over site. Change infusion tubing every 24 hours, or as per institutional policy.
Monitor for respiratory depression.	Monitor vital signs, especially respirations, per institutional policy. Pulse oximetry and apnea monitoring may be used, as per institutional policy. Within pediatrics, infants <1 year are often placed in a nurse-monitored room for closer observation and monitoring.
Prevent complications.	Assess for potential side effects, such as pruritus, nausea, and vomiting. Administer appropriate treatments to manage side effects as ordered and required.
Maintain urinary and bowel function.	Monitor intake and output. Assess for bladder and bowel distension. Assess for discomfort, frequency, and urgency. Some institutions will place a Foley catheter, which remains until the epidural is discontinued.

Various medications and routes of administration provide relief for patients with cancer pain. Long-acting or controlled-release medications have been successful in managing all types of chronic pain. These controlled-released medications (e.g., MS Contin, Roxanol SR, OxyContin) relieve pain for 8 to 12 hours. A 72-hour fentanyl patch is also available. Management of most chronic pain can be achieved with oral or patch medications.

Estimates of addiction in patients is difficult to determine. Nicholason and Passik (2007) suggested that the rate of addiction to opioids and alcohol is approximately the same as it is in the general population, ranging from 6% to 10%. In the acute care setting, the prevalence is higher because many medical illnesses such as cancer are complications of addictive disease (McCaffery et al., 2011). Patients with persistent pain requiring prolonged opioid administration sometimes develop an opioid tolerance. As a result, higher doses of opioids are required to attain pain relief. The higher opioid dose is not lethal because patients also develop a tolerance to respiratory depression. For patients with chronic pain, it is necessary to give required analgesics on a regular basis. Prescribing analgesics on a prn basis for chronic pain is likely to be ineffective and result in more suffering. The patient with chronic pain needs analgesics ATC, even when the pain subsides. Regular administration maintains therapeutic drug blood levels for ongoing pain control. Helping patients to understand this will help prevent breakthrough pain and loss of pain control.

Administering analgesics to treat chronic noncancer and cancer pain requires principles different from those used to treat acute pain. The WHO (1996) recommends a three-step approach to managing cancer pain (Figure 41-14). Therapy

Figure 41-14 WHO's pain relief ladder is a three-step approach to using drugs in cancer pain management. "+/- adjuvant," with or without adjuvant medications. **Source:** From World Health Organization. (1996). *Cancer pain relief with a guide to opioid availability*. Geneva, Switzerland: Author. Retrieved from <http://whqlibdoc.who.int/publications/9241544821.pdf>. Figure also available at <http://www.who.int/cancer/palliative/painladder/en/>.

begins with using NSAIDs, adjuvants, or both and progresses to strong opioids if pain persists. However, when a patient with cancer first experiences pain, it is recommended to begin with a higher dosage than will be needed for continued pain relief. The physician can then slowly decrease the dosage to the amount needed, ensuring immediate pain relief. Side effects of analgesia, such as nausea and constipation, can be aggressively treated so that analgesia can be continued. Patients may become tolerant to the side effects of nausea, but not to the constipating effects of analgesics. Stimulant laxatives should be routinely administered both to prevent and to treat constipation.

Transdermal drug systems administer fentanyl at predetermined doses for up to 48 to 72 hours. Fentanyl is about 100 times more potent than morphine.

safety alert Fentanyl should be used only in patients who are opioid-tolerant.

The transdermal route is useful when patients are unable to take drugs orally. Patients find these systems easy to use, and they allow for continuous opioid administration without needles or pumps. Self-adhesive patches release the medication slowly over time, achieving effective analgesia. You will need to exercise caution when administering transdermal patches to adult patients who weigh less than 45 kg (too little subcutaneous tissue for absorption) or who are hyperthermic. Hyperthermia causes more rapid drug absorption. The patch should never be cut or folded as this alters the drug-releasing mechanism (Pasero, Quinn, et al., 2011). The patches remain in place for 48 to 72 hours, and sites should be rotated with each change. The transdermal patch is generally applied to the back, flank, chest, or upper arm and is deemed to be safe for long-term therapy. Care providers should utilize plastic gloves while manipulating the patches so as to avoid inadvertent absorption of the fentanyl. Medication disposal procedures should be followed within institutions and proper disposal in the home environment to avoid the potential for misuse by other parties and to minimize environmental contamination (Pasero, Quinn, et al., 2011).

A transmucosal fentanyl "unit" (it resembles a lozenge on a handle) has been developed to treat breakthrough pain—a transient flare of moderate to severe pain superimposed on continuous or persistent pain—in opioid-tolerant patients (Box 41-16). Place the unit in the mouth and swab over the buccal mucosa and lower gums. The unit must remain intact to dissolve in the mouth, allowing 15 minutes for absorption. Use no more than two units per breakthrough pain episode. If the patient's pain is not relieved after two units, notify the physician.

Analgesics may be given rectally when patients have nausea and vomiting or are fasting before or after surgery (Pasero, Quinn, et al., 2011). This route is contraindicated if patients have diarrhea or if cancerous lesions involve the anus or rectum. Morphine, hydromorphone, and oxycodone are available as suppositories.

Another way to treat severe cancer pain in the home or acute care setting is with continuous infusions or a basal rate on a PCA device. This provides improved, uniform pain control with fewer peaks and valleys in plasma concentration, more effective drug action, and lower drug dosages overall. Candidates for continuous infusions include patients with

► BOX 41-16 Subtypes of Breakthrough Pain

1. Incident pain: Cause of pain is generally identifiable but occurrence may be unpredictable.
 - a. Predictable incident pain: Something identifiable, such as movement, predictably causes the pain.
 - b. Unpredictable incident pain: Occurrence of pain is unpredictable and may be caused by events such as bladder spasm. Occurs spontaneously.
2. Idiopathic pain: Cause is not readily identifiable.
3. End-of-dose: An increase in baseline pain that occurs prior to a scheduled dose of around-the-clock analgesic. Onset is usually gradual, and duration may be longer than that of incident or idiopathic pain.

Sources: Pasero, C., & McCaffery, M. (2011). *Pain assessment and pharmacological management* (p. 101). St Louis, MO: Mosby/Elsevier. Data from Bennett, D., Burton, A. W., Fishman, S., Fortner, B., McCarberg, B., Miaskowski, C., ..., Wong, W. (2005). Consensus panel recommendations for the assessment and management of breakthrough pain: Part 1: Assessment. *Pharmacology & Therapeutics*, 30(5), 296–301.

severe pain for whom oral and injectable medications provide minimal relief, patients with severe nausea and vomiting, and patients unable to swallow oral medications. The intramuscular route should not be used for controlling cancer pain because the injection itself is painful and absorption of the drug is inconsistent and erratic.

When a patient is first given continuous-drip morphine, it is essential that the IV access be patent and that the IV site be without complications (see Chapter 39). A central line catheter such as a Groshong or Hickman catheter, an implanted venous access port, or a peripherally inserted central catheter (PICC) is usually best suited for long-term IV infusion. When IV access is poor, the subcutaneous route with a concentrated dose is possible.

Barriers to Effective Pain Management. Barriers to effective pain management are complex and can involve the patient, health care provider, and health care system (Box 41-17). A deep-seated and often inappropriate concern shared by health care providers and patients is the fear of addiction when long-term opioid use is prescribed to manage pain. Differences exist between **physical dependence**, **addiction**, and **drug tolerance** (Box 41-18). Experiencing a physical dependency does not imply addiction, and drug tolerance in and of itself does not constitute addiction. Nurses and other health care providers need to avoid labelling patients as “drug seeking” because this term is poorly defined and may negatively affect their care. If you are concerned that a patient is abusing opioids, you have a responsibility to assess addictive issues and engage in a frank discussion with the patient. You should also notify the primary health care provider, explaining the reasons for your unease. You and your team could consider using an opioid contract, a written agreement between a sole prescribing physician and the patient that outlines key points regarding opioid therapy or daily dispensing with a maximum number of pills allotted per day (NOUGG, 2010a). Mehta and Langford (2006) have published recommendations for the management of acute pain in patients who are dependent on opioids but not necessarily addicted.

Individuals with an active addictive disorder or a history of substance abuse are at increased risk of poorly managed

► BOX 41-17 Barriers to Effective Pain Management

Barriers for Patients

Fear of addiction
 Worry about side effects
 Fear of tolerance (drug will be unavailable when needed)
 Concern that patient takes too many pills already
 Fear of injections
 Concern about not being a “good” patient
 Not wanting to worry family and friends
 More tests may be needed
 Belief that one needs to suffer to be cured
 Belief that pain is punishment for past indiscretions
 Inadequate education
 Reluctance to discuss pain
 Belief that pain is inevitable
 Belief that pain is part of aging
 Fear of disease progression
 Belief that health care team members are already doing all that they can
 Fear that patient will forget to take analgesics
 Fear of distracting physicians from treating illness
 Belief that physicians have more important or ill patients to see
 Belief that suffering in silence is noble and expected

Barriers for Health Care Providers

Concern that patient did not receive adequate pain assessment
 Concern about addiction
 Opiophobia (fear of opioids)
 Fear of legal repercussions
 No visible cause of pain exists
 Belief that patients must learn to live with pain
 Reluctance to deal with side effects of analgesics
 Not believing patient's report of pain
 Fear of giving a dose that will kill the patient
 Time constraints
 Belief that opioids may “mask” symptoms
 Belief that pain is part of aging or disease progression
 Overestimation of risks of respiratory depression
 Not viewed as ethical obligation to properly treat pain

Barriers for the Health Care System

Concern with creating “addicts”
 Ability to fill prescriptions
 Nurse practitioners and physician assistants not used efficiently
 Extensive documentation requirements
 Poor pain policies and procedures regarding pain management
 Lack of resources
 Inadequate access to pain clinics; long waiting lists for chronic pain clinics
 Poor understanding of economic impact of unrelieved pain

pain because of clinicians' attitudes, inadequate knowledge about addiction, and fears of exacerbating addiction by administering opioids. Poorly managed pain in these populations results in increased length of hospital stays and more frequent readmissions and outpatient and emergency department visits (Grant et al., 2007).

Placebos may be defined as “any medication or procedure, including surgery, that produces a beneficial effect in a patient because of its implicit or explicit intent, not because of its

► BOX 41-18

Definitions Related to the Use of Opioids for Pain Treatment

Physical Dependence

A state of adaptation that is manifested by a class-specific drug withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, or administration of an antagonist. It is not the same as addiction.

Drug Tolerance

A state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug's effects over time. It is not the same as addiction.

Addiction

A neurobiological disease that has genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviours that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.

Pseudoaddiction

Patient drug-seeking behaviours that may occur when pain is undertreated.

Approved by the Boards of Directors of the American Academy of Pain Medicine, The American Pain Society, and the American Society of Addiction Medicine. February 2001.

specific physical or chemical properties" (McCaffery et al., 2011, p. 42). Administration of a medication at a known subtherapeutic dose is also considered a placebo (Sullivan et al., 2005). Placebos are often appropriately used as controls in randomized controlled drug trials. However, the use of placebos to treat pain is considered unethical and deceitful (McCaffery et al., 2011) and sets up an adversarial relationship between the care providers and the patient and his or her family. If a placebo is ordered, you must question the order and ask, "Why?" Many health care agencies have policies that limit placebo use only to research.

Restorative and Continuing Care

Pain Clinics, Palliative Care, and Hospices. In recent years, health care providers have recognized pain as a significant health problem and, as a result, a number of programs and pain clinics have been developed. A comprehensive pain centre can treat patients on an inpatient or outpatient basis, conduct research into new treatments, and train professionals. Clinicians from various health disciplines, such as pharmacists, nurses, physicians, physiotherapists, pastoral care workers, nutritionists, and social workers, work with patients to discover effective pain-relief measures from a holistic perspective. Many hospitals have palliative care teams to assist patients and families to manage their chronic or end-of-life pain and symptoms diseases. Learning to live fully with an incurable condition is one goal of palliative care (see Chapter 28). Patients and their family members need

Figure 41-15 Critical thinking model for pain relief evaluation.

ongoing assistance in managing the patient's pain at home. Some palliative care programs have a pain and symptom management team whereby they may be consulted for complex pain and symptom problems.

In Canada, palliative and end-of-life care are burgeoning practice and research fields. The Canadian Institutes of Health Research (CIHR) support research and program development in these clinical areas. A hospice provides specialized end-of-life care in the patient's home or at a facility (see Chapter 28), helping patients with life-limiting illnesses to continue to live at home in comfort and privacy, with effective pain control as one of the priorities (Mehta et al., 2010). Under the guidance of hospice nurses, families learn to monitor patients' symptoms and become their primary caregivers. A hospice patient may become hospitalized in the event of a brief, acute care crisis or family problem.

❖Evaluation**Patient Care**

Evaluating pain is one of many nursing responsibilities that require critical thinking (Figure 41-15). The patient's behavioural responses to pain-relief interventions are not always obvious. Evaluating the effectiveness of a pain intervention requires that you be an intent observer and know what responses to anticipate on the basis of the type of pain, the type of intervention, the timing of the intervention, the physiological nature of the injury or disease, and the patient's previous

responses. Your evaluation involves psychological as well as physiological responses to pain.

If a patient continues to have discomfort after an intervention, try a different approach. For example, if an analgesic provides only partial relief, consider adding relaxation or guided-imagery exercises. Consult with the physician about increasing the dosage, decreasing the interval between doses, or trying different analgesics. Also evaluate tolerance to therapy and the overall relief obtained. If an intervention aggravates discomfort, stop it immediately and seek an alternative. Time and patience are necessary to maximize the effectiveness of pain management. Evaluate the entire pain experience to determine the most effective interventions and times for medication administration.

Patient Perceptions

The patient, if able, is the best resource for evaluating the effectiveness of pain-relief measures. You must continually assess whether the character of the patient's pain changes. The family can be a valuable resource, particularly if the patient has cancer or is noncommunicative and may not be able to express discomfort during the latter stages of terminal illness. Treating pain is successful when the patient's expectations of pain relief are met. Recall, however, that some patients may experience pain needlessly because they accept suffering and because they lack knowledge of available pain-relief interventions.

Pain assessment and responses to intervention should be accurately documented so that they can be communicated to the health care team. Communication occurs from nurse to nurse, shift to shift, and nurse to other health care providers. The nurse caring for the patient is responsible for reporting what has been effective for managing pain. Various bedside tools, such as a pain management flow sheet, help centralize information about pain management. Patients expect you to be sensitive to their pain and to be diligent in managing that pain. Because pain relief is a team effort, communicate effectively with all members, including the patients' family and significant others, to seek a collaborative approach and determine optimal treatment goals (Box 41-19).

❖ KEY CONCEPTS

- Pain is a purely subjective physical and psychosocial experience.
- A nurse's misconceptions about pain may result in doubt about the degree of the patient's suffering and in unwillingness to provide relief.

- Knowledge of the nociceptive pain processes of the pain experience—transmission, transduction, perception, and modulation—will provide you with guidelines for determining pain-relief measures.
- An interaction of psychological and cognitive factors affects pain perception.
- A person's cultural background influences the meaning of pain and how it is expressed.
- It is common for older patients not to report pain.
- Patients who have chronic pain are unlikely to show behavioural changes.
- Do not collect an in-depth pain history when the patient is experiencing severe discomfort.
- Pain can cause physical signs and symptoms similar to the signs and symptoms of other diseases.
- Patients waiting to undergo invasive tests may gain some pain relief from anticipatory guidance.
- Individualize your pain interventions by collaborating closely with the patient, using assessment findings, and trying a variety of interventions.
- Eliminating sources of painful stimuli is a basic nursing measure for promoting comfort.
- Use a regular schedule for analgesic administration, as this is more effective than an as-needed schedule in controlling pain.
- A patient-controlled analgesic device gives patients pain control, with low risk of overdose.
- While caring for a patient who receives local anaesthesia, protect the patient from injury.
- When administering epidural analgesia, take steps to prevent infection and monitor closely for respiratory depression.
- Your primary goal in pain management is to anticipate and prevent pain, rather than to treat it.
- In evaluating the effectiveness of a pain intervention, consider the changing character of pain, the patient's response to the intervention, and the patient's perceptions of a therapy's effectiveness.

❖ CRITICAL THINKING EXERCISES

1. Do you have a friend or family member who lives with cancer and is willing to talk about it? If so, ask the individual to tell you about different painful experiences they may have had and what he or she would recommend to help nurses provide better care during these painful events.
2. Madeleine Tremblay is a 40-year-old woman newly diagnosed with fibromyalgia. She is married and has a daughter and son, who are two and five years old, respectively. Her husband travels frequently and is often home only on weekends. Mrs. Tremblay tells the nurse: "The pain is so bad at night that I only get three or four hours of sleep. I have no opportunity to rest during the day because I'm busy caring for my children. I am so tired that I don't know how I am going to cope with this pain long-term." Identify two follow-up care plan components that would be important when considering Mrs. Tremblay's concerns regarding the management of her pain.
3. Alexis, aged three years, is admitted to the pediatric unit for a third-degree burn to her right lower extremity. How would you proceed in assessing this child's pain?
4. Mrs. Gorsky, an 83-year-old woman with metastatic breast cancer to the bone, has been receiving IV morphine for a week for severe back and leg pain. Her frequently increased infusion of morphine is not reducing her pain to an acceptable level, and she is becoming increasingly sedated. What other pharmacological interventions might be considered?

► BOX 41-19

Establishing a Collaborative Team Approach to Pain Management

1. Establish common goals for pain relief and optimal functioning.
2. Use common language regarding pain assessment and management.
3. Use validated pain-rating scales.
4. Secure a common knowledge base and encourage the use of clinical practice guidelines.
5. Optimize regular team communication opportunities for direct communication and problem solving.

Data from Arnstein, P. (2010). *Clinical coach for effective pain management*. Philadelphia, PA: F. A. Davis; and Pasero, C., & McCaffery, M. (2011). *Pain assessment and pharmacological management*. St Louis, MO: Mosby/Elsevier.

✦ REVIEW QUESTIONS

- As one of the strategies used to help relieve Mme Bouclair's pain during a dressing change, the nurse encourages her to concentrate on a favourite vacation setting. What is this non-pharmacological pain intervention known as?
 - Recall
 - Distraction
 - Imagery
 - Relaxation exercises
- A patient complains of pain in a cutaneous site that is different from where it originates. How does the nurse document this pain?
 - Transient pain
 - Superficial pain
 - Phantom pain
 - Referred pain
- Jacobie is a cooperative five-year-old Inuit boy who had abdominal surgery 24 hours ago. Which of the following validated pain assessment tools would be the most appropriate for the nurse to use to assess this child's pain?
 - FLACC
 - Numerical Rating Scale
 - The Northern Pain Scale
 - Wong-Baker FACES Scale
- Which one of the following responses would the nurse expect to assess as a physiological response to moderate pain?
 - Restlessness
 - Decreased heart rate
 - Increased blood pressure
 - Protection of the painful area
- Mr. Kumar, an 82-year-old man with Alzheimer's disease, is restless and moaning. His daughter states that he did not sleep well most of the night. Which one of the following actions is the most appropriate initial nursing response?
 - Obtain a psychiatric evaluation.
 - Administer pain medication as ordered.
 - Recommend giving the patient sleeping medication.
 - Assess and document physical and behavioural data.
- Mrs. Young requests medication for her abdominal incision pain, which she rates as 5 (scale of 0 to 10, with 10 being the worst pain). One hour after administration of her pain medication, she is able to walk in the hall for 10 minutes and rates her pain as a 2/10. Which one of the following interpretations about the dosage of pain medications is the most appropriate?
 - Adequate
 - Excessive
 - Insufficient
 - Unnecessary
- Which one of the following nursing actions is the most appropriate when a patient is anticipating a painful procedure?
 - Discuss analgesic options with the physician.
 - Inform the patient that the discomfort will be minimal.
 - Teach about the procedure and its associated discomfort.
 - Provide education about the procedure but avoid the associated discomfort.
- Relaxation and guided imagery are examples of which one of the following?
 - Adjuvants
 - Physical interventions
 - Patient-controlled analgesia
 - Cognitive-behavioural interventions
- The Canadian Pain Society recommends which method of opioid administration if pain is anticipated for the majority of the day?
 - On an as-needed (prn) basis
 - With complementary therapies
 - On an around-the-clock (ATC) basis
 - When the pain tolerance level is exceeded
- Patient-controlled analgesia (PCA) is often used for postoperative and cancer pain management for which one of the following reasons?
 - To improve nursing control over opioid administration
 - To promote sustained pain relief, with the patient in control
 - To enable family members to administer the drug dosage
 - To decrease the quantity of opioid medication use

✦ RECOMMENDED WEB SITES

Health Canada: <http://www.hc-sc.gc.ca/index-eng.php>

Health Canada provides an extensive listing of clinical guidelines for nurses in primary care. It provides the public, clinicians, and researchers with information on pain and other public health concerns, such as this document outlining questions, issues, and research surrounding neuropathic pain.

Canadian Pain Society: <http://www.canadianpainsociety.ca/en/> or <http://www.canadianpainsociety.ca/fr/>

The Canadian Pain Society is an association whose members include physicians, nurses, and other clinicians involved with the management of pain. Its aim is to foster and encourage research on pain, to promote education and training in the field of pain, and to improve the management of patients with acute and chronic pain.

The University of Toronto Centre for the Study of Pain: <http://www.utoronto.ca/pain/>

The University of Toronto Centre for the Study of Pain is a partnership involving the faculties of dentistry, medicine, nursing, and pharmacy. The mission of the centre is to lead, both nationally and internationally, in pain research, education, knowledge translation, networking, and sustainability.

International Association for the Study of Pain (IASP): <http://www.iasp-pain.org/>

The IASP is the leading professional forum for science, practice, and education in the field of pain. IASP brings together scientists, clinicians, health care providers, and policymakers to stimulate and support the study of pain and to use that knowledge for improved pain relief worldwide.

Canadian Hospice Palliative Care Association: <http://chpca.net/index>

This site is intended as an educational resource for professional and informal caregivers and interest groups. It includes an extensive listing of online resources for those interested in palliative and end-of-life care, including cancer, clinical, and research sites.

Registered Nurses' Association of Ontario: Assessment and Management of Pain: <http://www.rnao.org/Page.asp?PageID=924&ContentID=720>

The Registered Nurses' Association of Ontario's site is specific to nursing and is available in English and French. It features a number of best practice clinical guidelines, including those for the assessment and management of pain.

Canadian Cancer Society: <http://www.cancer.ca>

This site is an educational resource to help cancer patients and their caregivers. It has the most up-to-date knowledge and tools available related to cancer prevention, diagnosis, treatments, and supports and services. It also features a number of pain management publications, which include information on traditional and complementary therapies.

The Mayday Pain Project: <http://www.painandhealth.org/>

The Mayday Pain Project's goal is to improve pain assessment and care of patients nationally and internationally, particularly

for those living in rural, isolated areas. The site presents well-researched resources in a professional manner for educational purposes only.

Pain Treatment Topics: <http://pain-topics.org/>

This site is a noncommercial resource for health care providers and their patients, providing open access to clinical news, information, research, and education for a better understanding of evidence-informed pain-management practices.

Nutrition

Written by Kathryn Weaver, RN, PhD

Based on the original chapter by Patricia A. Stockert, RN, BSN, MS, PhD

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Explain the role of each major nutrient in proper nutrition.
- Explain the importance of maintaining a balance between energy intake and expenditure.
- List the end products of carbohydrate, protein, and fat metabolism.
- Explain the significance of saturated, unsaturated, polyunsaturated, and trans fats.
- Describe *Eating Well with Canada's Food Guide* and its value in planning nutritious meals.
- Specify recommended dietary intake for age and sex groups in Canada to ensure that patients meet the varied essential vitamins, minerals and nutritional requirements throughout their growth and development.
- Discuss the major methods of nutritional assessment.
- Identify three major nutritional problems, the patients who are at risk, and related nutrition therapy.
- Formulate a plan of care to help meet the specific nutritional needs of infants, toddlers, preschoolers, school-aged children, adolescents, adults, and older adults.
- Identify the potential nutritional deficits associated with vegetarian diets, with special consideration to vegan and ovo-lactate diets.
- Discuss diet counselling and patient teaching in relation to patient expectations.
- State the goals of enteral and parenteral nutrition.
- Describe the procedure for initiating and maintaining tube feedings, and avoiding related complications.

The chapter author would like to thank Brenda Mercer, BN, MN student; Patti Gallagher, RN, MN; Mary Lynn Clark, BN, RN; Olive Steeves Babineau, BN, RN; Gary Love, Speech Language Pathologist; Nicole Irving, BN, MN student; and Debbie Bastien, RN, BScN, MIDST(c) for their assistance with this chapter.

Proper nutrition and food safety—important to all Canadians—are a shared responsibility among government, industry, health providers, and consumers. Food supplies energy to accomplish everyday activities, building and repairing tissues and regulating organs and systems while helping to prevent the contraction of certain diseases and aid in the recovery from other diseases. One of the best ways to protect and promote good health is to ensure a nutritious and balanced diet. Food also holds symbolic meaning for many cultures and communities. Ceremonies, social gatherings, and religious events happen within the background of giving or taking food significant to the event. With such a complexity of meanings embedded in the food we eat, it is no wonder that the withholding of food, even in the form of intravenous (IV) nutrients, during a terminal illness reflects the symbolic power that food has over life and death.

Over a century ago, the mother of modern nursing, Florence Nightingale (1858), instructed nurses to maintain knowledge of the patient's diet: "Consider, remember how much he [or she] has had, and how much he [or she] ought to have" (p. 39). As nurses today, our role in promoting proper nutrition, diet therapy, and health continues to be vital. We must pay as much attention to our patients' diets as to their illnesses, treatments, and therapies. With advances in science, trends in illnesses and demographics, and the explosion of media attention on weight and fitness, our role in addressing diet-related issues has expanded. For example, in illnesses such as type 1 diabetes mellitus, a common health concern across Western nations, diet can be a major treatment and nurses the key professionals responsible for educating patients and families about food choices and available technology (e.g., insulin pumps) that influence the course of the disease and assist in self-care management (Canadian Diabetes Association [CDA], 2009). Along with type 1 diabetes, other conditions, such as type 2 diabetes, hypertension, and inflammatory bowel disease, require highly specialized nutritional support protocols, including diets low in sugars, cholesterol, or salt (Hypertension Canada, 2010).

Overall, the nutritional health of Canadians is good in comparison to that of other developed countries. This story may be changing, however, as evolving demographic and economic issues result in less time and fewer resources available for food-related activities. These issues include the rising poverty rate, a decline in resources available to rural communities, the aging of the population, and the social isolation or marginalization of certain groups of citizens. Rates of stay-at-home spouses have dropped significantly to 10% of Canadian households, leaving the majority of preschool children in day care or school while parents work. Unemployment rates have risen, and reduced-income earners now reflect a Canadian population facing economic difficulties such as accumulated debt, household budget deficits, and restricted choices for purchasing power. One in ten Canadian children, more than a million, lives below the poverty line according to the *2010 Report Card on Child and Family Poverty in Canada* (Campaign 2000, 2010). Statistics Canada (2010a) has indicated that a larger portion of the Canadian population is entering retirement age, and these older adults are choosing to stay in their own homes longer, placing them at risk for poor nutrition associated with mobility impairments and social isolation. In addition, between 2001 and 2006, Canada's Aboriginal population increased by 20.1% of the total population (Health Canada, 2010d); this is significant because Aboriginal children account for approximately

5% of all children in Canada (Ball, 2008) with one in every four Aboriginal children living below the poverty line (Campaign 2000, 2010). Canada's population is no longer predominantly White; about 133,900 of the 236,800 immigrants entering the country in 2007 came from the continent of Asia, representing more than half (56.5%) of all immigrants (Statistics Canada, 2010b). All these factors, along with the larger international issues arising from free trade and globalization, influence the nutritional health of Canadians.

One trend that has taken on alarming proportions is the increase in overweight and obesity. In 2004, approximately 59% of adult Canadians were overweight or obese (Statistics Canada, 2004). By 2009, about 18% of Canadian adults, or roughly 4.4 million people, reported height and weight that classified them as obese. This was up from 15% reported in 2004 (Statistics Canada, 2010c). Likewise, the prevalence of overweight or obesity in children has soared. Type 2 diabetes, an illness largely preventable through healthy eating and weight management that in the past occurred mainly in older individuals (Canadian Paediatric Society, 2005), is now being diagnosed in Canadian children as young as eight years of age (CDA, 2011a). Among Aboriginal people, rates of type 2 diabetes are three to five times higher than those of the general population (Health Canada, 2010d). Factors adversely affecting the nutritional health of today's Canadian society are serious, and the resultant conditions border on epidemic proportions. It is critical that nurses acquire nutritional knowledge to apply to the complexities of diseases, diverse populations, and current demographics (age, gender, income level, and culture).

Scientific Knowledge Base

Nutrients: The Biochemical Units of Nutrition

The body requires fuel to provide energy for the chemical reactions that enable cellular growth and repair, organ function, and body movement. The energy requirement of a person at rest is called the **basal metabolic rate (BMR)**. This is the energy needed to maintain life-sustaining activities (breathing, circulation, heart rate, and temperature) for a specific period of time. The **resting energy expenditure (REE)** is a measurement that accounts for BMR plus energy to digest meals and perform mild activity. REE is a baseline of energy requirement accounting for approximately 60% to 75% of our daily needs. Factors of age, body mass, gender, fever, environmental temperature, pregnancy, lactation, starvation, stress, illness, injury, infection, activity level, thyroid function, or the use of certain drugs may affect energy requirements or metabolism.

In general, when energy requirements are completely met by kilocalorie (kcal) intake in food, weight does not change. A kilocalorie is the unit of energy required to raise one kilogram of water by 1°C (referred to as "calorie" by the general public). When the kilocalories ingested exceed energy demands, a person gains weight. If the kilocalories ingested fail to meet energy requirements, a person loses weight.

Nutrients are the elements supplied by food that are necessary for body processes and function. Energy needs are met from three categories of nutrients: carbohydrates, proteins, and fats. Other nutrients are water, vitamins, and minerals, which do not provide energy but contribute to metabolic processes, including acid-base balance. A nutrient is considered essential if the body cannot manufacture it in a sufficient quantity to meet metabolic demands.

Foods are described according to **nutrient density**, the proportion of essential nutrients to the number of kilocalories. High nutrient-density foods, such as fruits and vegetables, provide a large number of nutrients in relation to kilocalories. Low nutrient-density foods, such as alcohol or refined sugar, are high in kilocalories but nutrient poor.

Foods may also be described as functional, fortified, or genetically modified. Foods are considered **functional** when a biologically active substance is added; for example, probiotics, such as bacterial cultures added to yogurt or juices (Paulionis, 2008; Verschuren, 2002). **Fortified** foods contain vitamins or minerals added during processing to increase the daily value by as much as 10% or 20%. Current fortification practices require the addition of vitamin D to milk to combat the childhood disease of rickets and the addition of folic acid to flour to reduce birth defects (Health Canada, 2005a). Although fortification has shown marked improvements in intakes of vitamin A, vitamin C, magnesium, folate, and calcium for some age and sex groups, fortification of other nutrients may be unnecessary when not based on an assessment of current nutrient intake patterns (Sacco & Tarasuk, 2009). The term **genetically modified** refers to the practice of pasting the genes of one organism into another organism often to resist disease and develop desired characteristics, such as a hardier texture, higher nutritional value, or faster growth (Health Canada, 2010f).

Carbohydrates. Carbohydrates are the recommended main source of energy in the diet. Each gram of carbohydrate produces 4 kcal and serves as the main source of fuel (glucose) for the brain, skeletal muscles during exercise, red and white blood cell production, and cell function of the renal medulla. Carbohydrates are obtained primarily from plant foods, except for lactose (milk sugar), and are classified according to their carbohydrate units, or **saccharides**.

Monosaccharides such as glucose (dextrose) or fructose (fruit sugar) are the building blocks of all other carbohydrates and cannot be broken down into a more basic carbohydrate unit. Disaccharides such as sucrose, lactose, and maltose are composed of two monosaccharides minus one unit of water. Both monosaccharides and disaccharides are classified as **simple carbohydrates** called *sugars*. Polysaccharides are composed of many carbohydrate units and are classified as **complex carbohydrates**. They include starch (stored form of glucose in plants) and glycogen (stored glucose in animals and humans). Some polysaccharides cannot be digested because humans do not have enzymes capable of breaking them down. Insoluble fibres are not digestible and include cellulose, hemicellulose, and lignin. Soluble fibres include pectin, guar gum, and mucilage. Dietary fibre is important to disease prevention, as it decreases low-density lipoprotein (LDL) cholesterol associated with the development of heart disease (Schlenker & Long, 2011).

Carbohydrate-rich foods are ranked according to their **glycemic index**, the effect on blood glucose levels and insulin response (CDA, 2011b). Carbohydrates that release glucose rapidly into the bloodstream (e.g., white bread, candy) have a high glycemic index. Carbohydrates that produce only small fluctuations in blood glucose (e.g., barley, lentils) have a low glycemic index and offer long-term health benefits of sustaining weight loss, prolonging physical endurance, and reducing risks associated with heart disease and diabetes.

Proteins. Proteins are essential for synthesis (building) of body tissue in growth, maintenance, and repair. Collagen, hormones, enzymes, immune cells, DNA, and RNA are all

composed of protein. In addition, blood clotting, fluid regulation, and acid-base balance require proteins. Nutrients and many pharmacological substances are transported in the blood by proteins.

The simplest form of protein is the amino acid. As with other nutrients, **essential amino acids** are those that the body cannot synthesize but must have provided in the diet. **Nonessential amino acids** can be synthesized by the body. **Amino acids** are linked together by peptide bonds to form larger protein molecules called polypeptides. Simple proteins such as albumin and insulin contain only amino acids or their derivatives. The combination of a simple protein with a nonprotein substance produces a more complex protein, such as lipoprotein, formed by a combination of a lipid (fat) and a simple protein.

Protein quality is determined by the balance of essential amino acids. Incomplete proteins lack a sufficient quantity of one or more essential amino acids and include cereals, legumes (beans, peas), and vegetables. A complete protein contains all of the nine essential amino acids in sufficient quantity to support growth and maintain nitrogen balance. Examples of foods that contain complete proteins are chicken, soybeans, fish, and cheese. Complete proteins are referred to as high-quality proteins. **Complementary proteins** are pairs of incomplete proteins that, when combined, supply the total amount of protein provided by complete protein sources.

Protein is the only major nutrient that contains nitrogen (it is 16% nitrogen) and is the only source of nitrogen for the body. Thus, nitrogen can be used to determine protein balance in the body. **Nitrogen balance** is achieved when the intake and output of nitrogen are equal. When the intake of nitrogen exceeds the output, the body is in positive nitrogen balance, which is required for growth, normal pregnancy, maintenance of lean muscle mass and vital organs, and wound healing. The nitrogen retained by the body is used for the building, repair, and replacement of body tissues. Negative nitrogen balance occurs when the body loses more nitrogen than it gains—for example, with severe infection, burns, fever, starvation, head injury, and trauma. The increased nitrogen loss is the result of body tissue destruction or loss of nitrogen-containing body fluids through urine, feces, sweat, and, at times, bleeding or vomiting. Nutrition during this period must provide nutrients to put patients into positive balance for healing.

Protein can be used to provide energy (4 kcal/g), but because of protein's essential role in growth, maintenance, and repair, adequate kilocalories should be provided in the diet from nonprotein sources. Protein is spared as an energy source when carbohydrate in the diet is sufficient to meet the energy needs of the body.

Fats. Fats (**lipids**) are the most calorically dense nutrient, providing 9 kcal/g. In addition to serving as fuel that supplies energy, fat cushions vital organs, lubricates body tissue, insulates, and protects cell membranes. Fats are composed of glycerol and fatty acids. **Triglycerides** circulate in the blood and are made up of three fatty acids attached to a glycerol. **Fatty acids** are composed of chains of carbon and hydrogen atoms with an acid group on one end of the chain and a methyl group at the other. Fatty acids can be **saturated**, in which each carbon in the chain has two attached hydrogen atoms, or **unsaturated**, in which an unequal number of hydrogen atoms are attached and the carbon atoms attach to each other with a double bond. **Monounsaturated fatty acids** have one double bond, whereas

polyunsaturated fatty acids have two or more double carbon bonds. Most animal fats have high proportions of saturated fatty acids, whereas vegetable fats have higher amounts of monounsaturated and polyunsaturated fatty acids. The various types of fatty acids have significance for health and the incidence of disease and are referred to in the dietary guidelines from the Heart and Stroke Foundation, the Canadian Cancer Society, and the Canadian Diabetes Association.

Trans fatty acids have received attention for their role in the development of coronary artery disease, diabetes, infertility in women, and prostate cancer in men (Merchant et al., 2008; Salmerón et al., 2001). **Trans fatty acids** are formed by the partial hydrogenation of vegetable oils and are mostly found in prepared foods, snack foods, and margarines. Trans fats raise blood levels of so-called bad cholesterol (LDL-cholesterol), a risk factor for heart disease, while lowering blood levels of so-called good cholesterol (HDL-cholesterol) which protects against heart disease (Health Canada, 2008). Increased research and consumer awareness has led to mandatory nutrition labelling of trans fats in Canada since 2005. The acceptable macronutrient distribution range (AMDR), the range associated with reduced risk of chronic illness while providing essential intakes of total fat, is 20% to 35% for adults (American Dietetic Association and Dietitians of Canada, 2007). It is recommended that Canadians decrease their intake of the proportion of saturated and trans fatty acids. There is evidence of reductions in trans fats in margarines since new labelling regulations came into effect in Canada; however, trans fat reductions may be restricted to higher-priced margarines, a change that may have limited benefit for lower-income groups, who are at higher risk of heart disease (Ricciuto et al., 2009).

Cholesterol is often discussed in connection with fats, although it is a sterol, not a triglyceride (Schlenker & Long, 2011). It occurs naturally in animal foods but is also synthesized by the liver. Cholesterol deposits in blood vessel walls cause atherosclerosis, which is the underlying cause of coronary artery disease.

Water. Water is a critical component of the body because cell function depends on a fluid environment. Water makes up 60% to 70% of total body weight. The percentage of total body water is greater for lean people than for obese people because muscle contains more water than any other tissue except blood. Infants have the greatest percentage of total body water, and older people have the least. When deprived of water, a person cannot survive for more than a few days. Water helps regulate body temperature and acts as a solvent for nutrients and waste products. Water passes freely through membranes that separate body fluids inside (intracellular) and outside (extracellular) cells. Various water-transport proteins called **aquaporins** function as water-selective channels in many cells, altering the speed at which water crosses cell membranes and influencing conditions such as cataract formation and hypertension (Verkman, 2005).

Fluid needs are met by ingesting liquids and solid foods high in water content, such as fresh fruits and vegetables. Water is also produced during digestion when food is oxidized. In a healthy individual, fluid intake from all sources equals fluid output through elimination, respiration, and sweating (see Chapters 35 and 39). An ill person can have an increased need for fluid (e.g., with fever or gastrointestinal losses) and also a decreased ability to excrete fluid (e.g., with cardiopulmonary or renal disease), which may lead to the need to restrict fluid intake.

Vitamins. Vitamins are organic substances essential to normal metabolism. The body is unable to synthesize most vitamins in the required amounts and depends on dietary intake. The quantity of vitamins in food is affected by food processing, storage, and preparation. Vitamin content is usually highest in fresh foods used quickly after minimal exposure to heat, air, or water. Certain vitamins function as antioxidants that neutralize substances called free radicals, which are thought to produce oxidative damage to body cells and tissues and to increase a person's risk for various cancers. Vitamins with antioxidant properties include water-soluble vitamin C and fat-soluble beta-carotene and vitamins A and E (Schlenker & Long, 2011).

Fat-Soluble Vitamins. The fat-soluble vitamins (A, D, E, and K) can be stored in the body. With the exception of vitamin D, these vitamins are provided only through dietary intake. Vitamin D is provided by both dietary intake and synthesis in the body with exposure to sunlight. Canada's food guide recommends that adults consume 500 mL (2 cups) of milk each day in order to receive adequate vitamin D. Yet because vitamin D needs increase after the age of 50 and obtaining adequate vitamin D from the diet alone is very difficult, Health Canada (2010g) recommends that all adults over the age of 50 take a daily vitamin D supplement of 10 micrograms (mcg; 400 IU) in addition to following Canada's Food Guide. The body can store fat-soluble vitamins; therefore, **hypervitaminosis** can result from megadoses (intentional or unintentional) of supplemental vitamins, excessive amounts of vitamins in fortified food, and excessive fish oils.

Water-Soluble Vitamins. The water-soluble vitamins are vitamins C and B complex (which consists of eight vitamins: thiamine, riboflavin, niacin, vitamin B₆, folate, vitamin B₁₂, pantothenic acid, and biotin). Another element, choline, is sometimes classified as a B vitamin. Water-soluble vitamins are easily destroyed by cooking and must be provided in the daily food intake. Although water-soluble vitamins are not stored in the body, toxicity may still occur with vitamin megadoses.

Minerals. Minerals are inorganic elements essential to the body as catalysts in biochemical reactions. Minerals become part of the structure of the body and its enzymes. For example, iron becomes attached to protein globin to form hemoglobin, which enhances oxygen-carrying capacity. Minerals are classified as **macrominerals** when the daily requirement is 100 mg or more and as **microminerals** or **trace elements** when less than 100 mg is needed daily. The macrominerals are calcium, sodium, potassium, phosphorus, magnesium, sulphur, and chloride. Trace minerals include iron, iodine, fluoride, zinc, selenium, chromium, copper, manganese, molybdenum, and cobalt. Other trace minerals such as aluminum, cadmium, arsenic, and boron have possible but not clearly delineated nutritional functions. Arsenic, aluminum, and cadmium have toxic effects.

Anatomy and Physiology of the Digestive System

Digestion. Digestion of food consists of mechanical breakdown that results from chewing, churning, and mixing with fluid, as well as chemical reactions by which food is reduced to its simplest form. Each part of the gastrointestinal system has an important digestive or absorptive function (Figure 42-1).

Enzymes are an essential component of the chemistry of digestion. Enzymes are proteinlike substances that act as

Figure 42-1 Summary of digestive system anatomy and organ function. **Source:** From Rolin Graphics.

catalysts to speed up chemical reactions. Most enzymes have one specific function and function best at a specific pH. The secretions of the gastrointestinal tract have vastly different pH levels. For example, saliva is relatively neutral, gastric juice is highly acidic, and the secretions of the small intestine are alkaline.

The mechanical, chemical, and hormonal activities of digestion are interdependent. Enzyme activity depends on the mechanical breakdown of food to increase the surface area for chemical action. Hormones regulate the flow of digestive secretions needed for enzyme supply. The secretion of digestive juices and the motility of the gastrointestinal tract are also regulated by physical, chemical, and hormonal factors. Action in the gastrointestinal tract is increased by nerve stimulation from the parasympathetic nervous system (e.g., the vagus nerve).

Digestion begins in the mouth, where chewing mechanically breaks down food. The food is mixed with saliva, which contains ptyalin (salivary amylase), an enzyme that acts on cooked starch to begin its conversion to maltose. The longer food is chewed, the more starch digestion occurs in the mouth.

Proteins and fats are broken down physically but remain unchanged chemically because enzymes in the mouth do not react with these nutrients. Because simple sugars (monosaccharides) require no digestion, they may be absorbed from the mouth. Chewing reduces food particles to a size suitable for swallowing, and saliva provides lubrication to further ease swallowing of the food. The epiglottis is a flap of skin that closes over the trachea during swallowing to prevent **aspiration**. The tongue manoeuvres the mass of chewed food into the pharynx, which activates the swallowing reflex. Swallowed food enters the esophagus and is moved along by wave-like muscular contractions (**peristalsis**) to the base of the esophagus, above the cardiac sphincter. Pressure from a bolus of food at the cardiac sphincter causes it to relax, allowing the food to enter the fundus (uppermost portion) of the stomach. Difficulty swallowing is referred to as **dysphagia**.

In the stomach, pepsinogen is secreted by chief cells and then converted by hydrochloric acid (HCl) to pepsin, a protein-splitting enzyme. Gastric lipase and amylase are produced to begin fat and starch digestion, respectively. The stomach's pyloric glands secrete gastrin, a hormone that triggers parietal

cells to secrete intrinsic factor (IF) and HCl. IF is necessary for absorption of vitamin B₁₂ in the ileum. HCl also destroys bacteria, increases the absorbability of iron and calcium, and maintains the pH of the gastric juice. The lining of the stomach is protected from autodigestion by a thick layer of mucus. Alcohol and aspirin are two substances directly absorbed through the lining of the stomach. The muscular walls of the stomach produce a churning action that continues mechanical digestion. The stomach acts as a reservoir where food remains for approximately three hours, within a range of one to seven hours.

Food leaves the antrum, or distal stomach, via the pyloric sphincter and enters the duodenum as an acidic, liquefied mass called **chyme**. Chyme flows into the duodenum and is quickly mixed with bile, intestinal juices, and pancreatic secretions. Secretin and cholecystokinin (CCK) are hormones secreted by the mucosa of the small intestine. Secretin activates release of bicarbonate from the pancreas, raising the pH of chyme. CCK inhibits further gastrin secretion and initiates the release of additional digestive enzymes from the pancreas and gallbladder.

Bile is manufactured in the liver and stored in the gallbladder. Bile acts as a detergent, as it emulsifies fat to permit enzyme action while suspending fatty acids in solution. Pancreatic secretions contain six enzymes: amylase to digest starch; lipase to break down emulsified fats; and trypsin, elastase, chymotrypsin, and carboxypeptidase to break down proteins.

Peristalsis continues in the small intestine, mixing the secretions with the chyme. The mixture becomes increasingly alkaline, inhibiting the action of the gastric enzymes and promoting the action of the duodenal secretions. Epithelial cells in the inner walls of the small intestine secrete enzymes to facilitate digestion. These enzymes include sucrase, lactase, maltase, lipase, and peptidase. The major portion of digestion occurs in the small intestine, producing glucose, fructose, and galactose from carbohydrates; amino acids and dipeptides from proteins; and fatty acids, glycerides, and glycerol from lipids. Approximately five hours are required to pass food through the small intestine via peristalsis.

Absorption. The small intestine is the primary absorption site for nutrients. Its inner surface is lined with fingerlike projections called villi, which increase the surface area available for absorption. Nutrients are absorbed by means of passive diffusion, osmosis, active transport, and pinocytosis (Box 42-1).

The main source of water absorption is via the intestine. Approximately 7 L of gastrointestinal secretions and 1.2 L of oral intake, totalling 8.2 L of fluid, must be managed daily within the gastrointestinal tract. The small and large intestines reabsorb 8.1 L a day. The remaining 0.1 L is eliminated in feces. In addition to water, electrolytes and minerals are absorbed, and bacteria in the colon synthesize vitamin K and some B-complex vitamins. Finally, feces are formed in the colon for elimination.

Metabolism and Storage of Nutrients. Metabolism refers to all of the biochemical reactions within the cells of the body. Metabolic processes can be anabolic (building) or catabolic (breaking down). **Anabolism** is the production of more complex biochemical substances by synthesis of nutrients. Anabolism occurs when lean muscle is added to the body through diet and exercise. Amino acids are anabolized into tissues, hormones, and enzymes. **Catabolism** is the breakdown of biochemical substances into simpler substances.

► BOX 42-1

Mechanisms for Intestinal Absorption of Nutrients

Mechanism Definition

Active Transport

In this energy-dependent process, particles move from an area of greater concentration to an area of lesser concentration. A special "carrier" is needed to move the particle across the cell membrane.

Passive Diffusion

The force by which particles move outward from an area of greater concentration to lesser concentration constitutes passive diffusion. The particles do not need a special "carrier" to move outward in all directions.

Osmosis

In this process, water moves through a membrane that separates solutions of different concentrations. Water moves to equalize the concentration pressures on both sides of the membrane.

Pinocytosis

Large molecules of nutrients are engulfed by the absorbing cell when the molecule attaches to the absorbing cell membrane.

Data from Nix, S. (2005). *Williams' basic nutrition and diet therapy* (12th ed.). St Louis, MO: Mosby; and Williams, S. D., & Schlenker, E. D. (2011). *Essentials of nutrition and diet therapy* (10th ed.). St Louis, MO: Mosby.

Starvation is an example of catabolism, when wasting of body tissues occurs. Normal metabolism and anabolism are physiologically possible when the body is in positive nitrogen balance, whereas catabolism occurs during physiologic states of negative nitrogen balance.

Nutrients absorbed in the intestines, including water, are transported via the circulatory system to body tissues. Through the chemical changes of metabolism, nutrients are converted into a number of substances required by the body. Carbohydrates, protein, and fat undergo metabolism to produce chemical energy and to maintain a balance between anabolism and catabolism. To carry out the body's work, the chemical energy produced by metabolism is converted to other types of energy. For example, muscle contraction involves mechanical energy, nervous system function involves electrical energy, and the mechanisms of heat production involve thermal energy. All of these forms of energy originate in metabolism.

Nutrient metabolism consists of three main processes:

1. Catabolism of glycogen into glucose, carbon dioxide, and water (**glycogenolysis**)
2. Anabolism of glucose into glycogen for storage (**glycogenesis**)
3. Catabolism of amino acids and glycerol into glucose for energy (**gluconeogenesis**)

Glycogen, synthesized from glucose and stored in small reserves in liver and muscle tissue, provides energy during brief periods of fasting and maintains blood glucose levels as we sleep. Amino acids can be converted to fat and stored or catabolized into energy via gluconeogenesis. All body cells except red blood cells and neurons can oxidize fatty acids into **ketones** for energy in the absence of dietary carbohydrates (glucose). Some of the nutrients required by the body are stored in body tissues. The body's major form of reserve energy is fat, stored as adipose tissue.

Elimination. Chyme is moved by peristaltic action through the ileocecal valve into the large intestine, where it

becomes feces. As feces move toward the rectum, water is absorbed into the intestinal mucosa. The longer the material stays in the large intestine, the more water is absorbed, causing the feces to become firmer. Exercise and fibre stimulate peristalsis. Feces contain cellulose and similar indigestible substances, sloughed epithelial cells from the gastrointestinal tract, digestive secretions, water, and microbes.

Dietary Guidelines

Dietary Reference Intakes. In 1997, the Food and Nutrition Board of the American National Institute of Medicine/National Academy of Sciences, in partnership with Health Canada, developed **dietary reference intakes (DRIs)** with respect to age, sex, pregnancy, and lactation (Atkinson, 2011; Paulionis, 2008). The DRIs present evidenced-informed criteria for an acceptable range of minimum to maximum amounts of nutrients, vitamins, and minerals needed to avoid deficiencies or toxicities. The DRIs have four components: (1) the estimated average requirement (EAR), which is the recommended amount of a nutrient sufficient to maintain a specific body function for 50% of the population based on age and gender; (2) the recommended dietary allowance (RDA), which is the average needs of 98% of the population, not the exact needs of an individual (Murphy et al., 2006); (3) the upper intake level (UL), which is the highest level believed to pose no risk of adverse health events but is not a recommended level of intake (Beaton, 2006); and (4) the adequate intake (AI), which is the suggested intake for individuals based on observed or scientifically determined estimates of nutrient intakes and is used when insufficient evidence exists to set the RDA. Because this evidence is continually evolving, clinicians should consult current resources, such as Health Canada Web pages and other evidence-informed literature, when determining a patient's specific nutrition needs or supplementation.

Food Guidelines. In 1942, Health Canada developed Canada's first food guide, *Canada's Official Food Rules*. Since then, the food guide has undergone many changes in name, appearance, and content. However, its ultimate purpose—to inform daily food choices and promote optimal nutritional health—has not changed (Katamay et al., 2007). The current guide, called *Eating Well With Canada's Food Guide* (Health Canada, 2007b; Figure 42-2), is based on a range of scientific evidence resulting from focus groups, online consultations, regional meetings, and reviews of literature about the environmental context in which Canadians make food choices. Input from stakeholders (e.g., health professional groups, industry) and the public helped to ensure that the recommendations are scientifically sound and address those characteristics of the diet most relevant to the promotion of health and reduction of chronic disease (Health Canada, 2007b).

In developing Canada's Food Guide, food-group composites were used, and once nutrient goals (e.g., RDA, AI) were met for a given food intake pattern, additional testing was done to evaluate the adequacy of varied food choices consistent with the pattern. For example, a bagel, 375 mL of rice, and 30 g of breakfast cereal rather than six servings of a grain composite were used (Murphy & Barr, 2007). Random simulated diets were generated for each of nine age and gender groups. The prevalence of inadequacy was assessed for each nutrient with an EAR. If the prevalence of inadequacy was low, the recommended intake pattern was considered adequate in diets that deviated from the proportions of foods

included in the composites. If the prevalence of inadequacy was high, the food intake pattern was revised. Therefore, most people following the intake pattern listed in Canada's Food Guide have a high probability of meeting their nutritional requirements and a low probability of nutrient excess, even if their individual food choices vary (Katamay et al., 2007; Murphy & Barr, 2007).

Included in the general guidelines of *Eating Well With Canada's Food Guide* are specific suggestions for food choices. Consumers are told to make at least half their grain selections whole grain; eat at least one dark green and one orange vegetable per day; and use vegetables and fruits more than juice, which contains a lower amount of fibre. Lower-fat dairy products, lean meats, and choices from the lower-fat meat group (e.g., legumes, tofu) are suggested. The minimum intake of unsaturated fats is 30 to 45 mL. Two food-guide servings of fish each week are suggested on the basis of evidence relating fish consumption and reduced risk of cardiovascular disease. The Food Guide lists water as a calorie-free way to quench thirst and recommends that community water supplies be fluoridated to the level of 1 mg/L. Recommended intakes and nutritional values according to Canada's Food Guide are shown in Table 42-1.

Canada's Food Guide notes the importance of physical activity in maintaining energy balance and recommends that adults spend 30 to 60 minutes per day carrying out some physical activity and children and youth spend at least 90 minutes per day. The guide provides advice on the use of vitamin and mineral supplementation when the recommended food intake pattern does not ensure adequate amounts. Although not specified in the guide, Canadians are advised to limit salt to "healthy" levels, alcohol to no more than 5% of total energy, and caffeine to no more than 400 mg for the general population, no more than 300 mg (or a little over two 8-oz [237 mL] cups of coffee per day) for women of childbearing age, and no more than 2.5 mg/kg/day for children (Health Canada, 2010b).

Eating Well With Canada's Food Guide has been adapted for First Nations, Inuit, and Métis populations (Health Canada, 2007c). Examples of foods traditional to Canadian Aboriginal populations are wild plants and seaweed in the fruit and vegetable groups, bannock as a grain product, and wild game as a meat alternative. Included in the online Food Guide is a link to a government Web site for advice on limiting exposure to mercury from eating locally caught fish. Instructions are also given for including traditional fats in the diet such as seal and whale oil, ooligan grease, and bacon fat.

In the past, Canada's Aboriginal peoples subsisted on foods obtained from hunting, trapping, fishing, gathering, and agriculture. The resulting diet, high in animal protein and low in fat and carbohydrates, provided adequate energy and nutrients. In replacing traditional foods with contemporary market foods, the current diet of Aboriginal peoples is lower in iron, folacin, calcium, vitamins A and D, fibre, fruit, and vegetables and higher in fat and sugar intakes. Patterns of food consumption are further influenced by issues of **food security** (ability to acquire acceptable foods), preferences in body size, individual taste preferences, availability of particular species for food, knowledge of the nutritional deficits of store-bought food, and modification and contamination of the natural environment. Health problems such as anemia, dental caries, heart disease, obesity, and diabetes are related to such beliefs and dietary practices (Willows, 2005).

TABLE 42-1

Summary of Recommended Intakes and Nutritional Values According to *Eating Well With Canada's Food Guide*

Vegetables and Fruit		Grain Products		Milk and Alternatives		Meat and Alternatives	
2–3 years of age:	4 servings per day	2–3 years of age:	3 servings per day	2–3 years of age:	2 servings per day	2–8 years of age:	1 serving per day
4–8 years of age:	5 servings	4–8 years of age:	4 servings	4–8 years of age:	2 servings	9–13 years of age:	1–2 servings
9–13 years of age:	6 servings	9–13 years of age:	6 servings	9–13 years of age:	3–4 servings	Girls 14–18 years of age:	2 servings
Girls 14–18 years of age:	7 servings	Girls 14–18 years of age:	6 servings	14–18 years of age:	3–4 servings	Boys 14–18 years of age:	3 servings
Boys 14–18 years of age:	8 servings	Boys 14–18 years of age:	7 servings				
Women 19–50 years of age:	7–8 servings	Women 19–50 years of age:	6–7 servings				
Men 19–50 years of age:	8–10 servings	Men 19–50 years of age:	8 servings	Adults 19–51 years of age:	2 servings	Women 19–50 years of age:	2 servings
Adults 51+ years of age:	7 servings	Women 51+ years of age:	6 servings	Adults 51+ years of age:	3 servings	Men 19–50 years of age:	3 servings
		Men 51+ years of age:	7 servings			Women 51+ years of age:	2 servings
						Men 51+ years of age:	3 servings

Some Important Nutrients in the Food Groups

	Protein	Protein	Protein
Carbohydrate	Carbohydrate	Fat	Fat
Fibre	Fibre	Carbohydrate	
	Thiamin		Thiamin
	Riboflavin	Riboflavin	Riboflavin
	Niacin		Niacin
Folate	Folate		Vitamin B ₆
Vitamin B ₆		Vitamin B ₁₂	Vitamin B ₁₂
Vitamin C			
Vitamin A		Vitamin A	
		Vitamin D	
		Calcium	
	Iron		Iron
	Zinc	Zinc	Zinc
Magnesium	Magnesium	Magnesium	Magnesium
Potassium	Potassium	Potassium	Potassium

Adapted from Health Canada. (2007). *Eating well with Canada's food guide*. Ottawa, ON: Author. Retrieved from http://www.hc-sc.gc.ca/fn-an/food-guide-aliment/index_e.html. Reproduced with permission of the Minister of Public Works and Government Services Canada.

To date, Canada's Food Guide has not been modified to recognize the nutritional concerns of Chinese Canadians or other immigrant groups, although it has been translated into 10 languages. This omission has implications for people living in Toronto, Vancouver, and Montreal since they are the primary destinations for new Canadians (Citizenship & Immigration Canada, 2011). In a study designed to explore the cultural relevance of a fruit-and-vegetable questionnaire for adults from Toronto's Chinese-, Portuguese-, and Vietnamese-speaking communities (Paisley et al., 2005), participants commented on the absence of vegetables and fruits familiar to them. Canada's Food Guide cannot stand alone as a tool to inform new immigrants of healthy eating habits, and consideration should be given to supporting a network of professionals working with new immigrants to promote the sharing of information and

educational techniques (Martineau, 2008). The need for further examples of culturally appropriate foods and portions will, no doubt, be addressed through ongoing revisions to the Food Guide.

The Nutrition Label. Since December 12, 2007, mandatory nutrition labelling consisting of a nutrition facts table listing energy (calories) and 13 nutrients (fat, saturated fat, trans fat, cholesterol, sodium, carbohydrate, fibre, sugars, protein, vitamin A, vitamin C, calcium, and iron) has been required on most prepackaged foods in Canada. This easy-to-read table, which appears on food labels in a consistent appearance, provides consumers with the information necessary to make informed food choices and compare products (Figure 42-3). This information includes (a) the specific amount of the food item that makes up the serving size, an amount that may

Nutrition Facts		
Per 3/4 cup (175g)		
Amount	% Daily Value	
Calories 160		
Fat 2.5 g	4 %	
Saturated 1.5 g	8 %	
+ Trans 0 g		
Cholesterol 10 mg		
Sodium 75 mg	3 %	
Carbohydrate 25 g	8 %	
Fibre 0 g	0 %	
Sugars 24 g		
Protein 8 g		
Vitamin A	2 %	Vitamin C 0 %
Calcium	17 %	Iron 0 %

Figure 42-3 Example of food label. **Source:** Health Canada. (2008). *The nutrition facts table*. Ottawa: Author. Retrieved from <http://www.hc-sc.gc.ca/fn-an/label-etiquet/nutrition/cons/index-eng.php>. Reproduced with the permission of the Minister of Public Works and Government Services Canada.

differ from the Food Guide serving size, and (b) the percent daily value (% DV), a general guideline of how the food's nutrient content contributes to daily diet. It is important to note that the % DV is based on a 2000 calorie/day adult diet and thus does not address recommended nutrient intake for those who are pregnant or breastfeeding. The following diet-related health claims have been established from recognized health and scientific information:

- A healthy diet low in sodium and high in potassium may reduce high blood pressure risk.
- A healthy diet adequate in calcium and vitamin D may reduce the risk of osteoporosis.
- A healthy diet low in saturated fat and trans fat may reduce the risk of heart disease.
- A healthy diet rich in vegetables and fruit may reduce the risk of some types of cancer.

Some other nutrient content claims as regulated by the Canadian government (Canadian Food Inspection Agency, 2011) are the following:

- *Free* indicates that the number of calories or the amount of a nutrient is nutritionally insignificant in a specified amount of food.
- Claims for *saturated fatty acids* include a restriction on levels of both saturated and trans fatty acids.
- The claim (*naming the percent*) *fat-free* is allowed only if accompanied by the statement *low fat* or *low in fat*.
- The nutrient content claim *light* is restricted to foods that meet the criteria for either *reduced in energy* or *reduced in fat*.
- The only nutrient content claims permitted for foods for children under two years of age are *source of protein*, *excellent source of protein*, *more protein*, *no added sodium*, and *no added sugar*.

- A claim of *reduced in energy* or *reduced in calories* is allowed if the item has at least 25% fewer calories than the food to which it is compared.

Nutrition for Health: An Agenda for Action. In 1992, the World Health Organization (WHO) endorsed the World Declaration on Nutrition. This declaration set goals for each country to eliminate starvation and nutritional diseases and disorders (e.g., iodine and vitamin deficiency disorders) and to promote nutritional well-being of all people. Canada responded to this endorsement and devised *Nutrition for Health: An Agenda for Action* (Health Canada, 2002). This document is the combined work of multisectoral groups based on an analysis of Canada's current situation and focused on stimulating and accelerating all sectors to achieve healthier people. The challenge remains to motivate consumers to put the dietary recommendations into practice. For example, although Canadian awareness of trans fat surged from 45% in 1998 to 79% in 2005 (Field, 2008), awareness may not necessarily equate with understanding. An online national survey conducted by the American Heart Association in 2006 found that 84% of survey participants had heard of the term *trans fats*, but 50% of them did not understand the health effects and less than 50% could identify one food from a list as typically containing trans fats. Research is needed to determine the knowledge, attitudes, and behaviour of Canadian consumers to understand if they are translating the message on trans fats and other dietary recommendations into healthier choices. Health providers can play a key role in communicating guidelines to consumers and educating consumers on nutrition labelling.

Nursing Knowledge Base

Nutrition During Human Growth and Development

Infants Through School-Aged Children. Infancy is marked by rapid growth with high protein, vitamin, mineral, and energy requirements. The average (50th percentile) birth weight of a full-term (40-week gestation) Canadian newborn boy is currently 3613 g; that for a Canadian newborn girl, 3470 g (Kramer et al., 2001). The infant usually doubles birth weight at four to five months and triples it at one year. An energy intake of approximately 108 kcal/kg of body weight is needed in the first half of infancy and 98 kcal/kg in the second half (Tontisirin & de Haen, 2001). Commercial formulas and human breast milk both provide approximately 20 kcal/30 mL. A full-term newborn is able to digest and absorb simple carbohydrates, proteins, and a moderate amount of emulsified fat. Spitting up may occur during the first year until the gastroesophageal sphincter (which opens to allow food to enter the stomach and gas to escape after meals) matures and the child learns to sit independently (Hobbie et al., 2000). Infants need 100 to 150 mL/kg per day of fluid because a large portion of their total body weight is water.

Breastfeeding. The Canadian Paediatric Society Nutrition Committee, Dietitians of Canada, and Health Canada (Joint Working Group, 1998; reaffirmed February 2008) recommend breastfeeding as the optimal method of infant feeding. Breastfeeding confers immunological and allergy protection to the infant during the period of breastfeeding, is economical and convenient (breast milk is always fresh and at the correct temperature), and provides an excellent opportunity for mother and infant to interact (Health Canada, 2004a). Health Canada (2004a) and WHO (2001) recommend the exclusive use

of breast milk for the first six months of the infant's life. Breast-fed infants need supplemental vitamin D because breast milk has only 1 to 10 IU/250 mL (Health Canada, 2004b), or 60% of the vitamin D needed by infants under one year of age. Other vitamin or mineral supplementation is not recommended for the first six months (Health Canada, 2004b).

In 2007–2008, 87.9% of Canadian mothers breastfed or tried to breastfeed their last child (Health Canada, 2010a). The percentage of mothers who tried breastfeeding in the Atlantic Provinces and Quebec was significantly lower than the national average, while the breastfeeding initiation rate in British Columbia was significantly higher. The initiation rate increased with increasing age (e.g., fewer mothers aged 15 to 24 [82.9%] initiated breastfeeding than did mothers aged 35 to 55 [89.2%]); married and common-law status (89.4%) compared to widowed, separated, divorced, or single status (79.7%); residing in urban areas (88.7%) compared to rural areas (81.5%); and being of Asian (96.2%), Black (95.7%), or other, including Arab, West Asian, Latin American, other racial/cultural origin or multiple racial/cultural origin (93.5) ethnic or racial background compared to White (86.3%) or Aboriginal (81.5%). Despite these overall high initiation rates, by six months the Canadian rate for exclusive breastfeeding was at 18.7%, although 54% still offered some breastfeeding. To strengthen successful breastfeeding in Canada, health practitioners are encouraged to promote immediate mother–infant contact, exclusive breastfeeding, and on-demand feeding (Chalmers et al., 2009).

Formula. Commercially prepared infant formulas, cow's milk-based and iron fortified, are designed to contain the approximate nutrient composition of human milk. Protein in the formula is typically supplied as whey, soy, cow's milk base, casein hydrolysate, or elemental amino acids. The composition, processing, packaging, and labelling of all infant formulas are regulated under Canadian food and drug laws. Research shows that differences in the way certain constituents within formulas are absorbed may influence optimal growth and development. Infants fed formulas containing total potentially available nucleosides (TPAN), which prevent suppression of the immune system, increase resistance to some bacterial and fungal pathogens, and reduce the risk of diarrhea, experienced the same gastrointestinal tolerance as those receiving human milk (Health Odyssey International, 2008). Infants who were fed formulas containing palm and palm olein (PO) oils as the main source of fat excreted more calcium in their stools and had significantly lower bone mineral content than did infants fed the PO-free formula. Specialty formulas are indicated for infants with detected or suspected pathology. Health providers caring for new mothers and their infants can address mothers' concerns about infant formulas and help them make informed choices when selecting the best substitute for human milk.

Regular cow's milk should not be used in infant formula before 9 to 12 months of age because it may cause gastrointestinal bleeding, is too concentrated for the infant's kidneys, increases the risk of milk product allergies, and is a poor source of iron and vitamins C and E (Schlenker & Long, 2011). Honey is a potential source of botulism toxin and should not be used in the infant's diet, as the toxin can be fatal in children under one year of age (Schlenker & Long, 2011).

Introduction to Solid Food. Breast milk or formula provides sufficient nutrition for the first six months of the infant's life. After that, solids are introduced to meet the infant's nutrient needs, specifically, iron, zinc, and vitamin A.

Cues indicating readiness for solid foods are the appearance of fine motor skills of the hand and fingers, hand-to-mouth movement, interest in adult food and self-feeding, increased milk consumption, ability to move food to the back of the mouth, and ability to sit alone in a high chair. Puréed smooth foods are typically the first semi-solid food to be introduced to an infant. The addition of foods to an infant's diet should be governed by the infant's nutrient needs and physical readiness to handle different forms of foods and by the need to detect and control allergic reactions. New foods should be introduced one at a time, early in the day, at two-day intervals, or four to seven days apart if the child is known to have allergies (Alberta Health and Wellness, 2008). It is best to introduce new foods before milk or other foods to avoid infant rejection due to satiety (Health Canada, 2005b).

The growth rate slows during toddler years (ages one to three years). The toddler needs fewer kilocalories but an increased amount of protein in relation to body weight; consequently, appetite may decrease at about 18 months of age. Toddlers exhibit strong food preferences and become picky eaters. Small, frequent meals consisting of breakfast, lunch, and dinner, with three interspersed, nutrient-dense snacks, may improve nutritional intake (Hockenberry, 2004). Calcium and phosphorus are important for healthy bone growth. Whole milk should be used until the toddler reaches two years of age to help ensure adequate intake of fatty acids for brain and neurological development. Toddlers and preschoolers need vitamin D supplementation until their diet includes at least 10 mcg (400 IU) per day of vitamin D from other dietary sources (i.e., drinking two cups of milk daily and eating one to two servings of fish weekly). Toddlers who consume more than 720 mL of milk daily in lieu of other foods may develop milk anemia, as milk is a poor source of iron.

The oral health of infants and children needs to be focused on preventing cavities. Children who sleep with a bottle are at particular risk of developing early childhood tooth decay (ECTD), a severe type of tooth decay that can affect baby teeth, especially the upper front teeth. The sugars from the milk, juice, and drinks left in the mouth combine with bacteria in plaque to create an acid that damages the enamel of a tooth. The longer and more often food is left in the mouth, the greater the chance of developing ECTD (Health Canada, 2005c). Dental visits should begin within six months of the eruption of the first tooth or by one year of age at the latest. From the age of three years, twice-yearly dental inspections are recommended. Children under three years of age should have their teeth brushed by an adult, and parents need to supervise children less than six years of age during brushing (Canadian Dental Association, 2005).

Preschoolers' (three to five years old) dietary requirements are similar to those of toddlers. They consume slightly more than toddlers, and nutrient density is more important than quantity. Encouragement of healthy eating is an important goal of parenting, and parents should try to use attractive food presentations and fun, educational initiatives rather than unhealthy food as a reward (Alphabet Soup, 2005; Tucker et al., 2006). Because preschoolers have small stomachs, they need to eat small amounts of food more often throughout the day. One Food Guide serving from a food group can be divided into smaller amounts and served throughout the day. For example, half a serving of Meat and Alternatives may be served at two different meals such as one egg at lunch and about 30 g (1 oz) of chicken for dinner (Health Canada, 2011a).

safety alert Foods such as hot dogs, candy, gum, cough drops, raisins, sunflower seeds, fish with bones, peanuts, peanut butter, marshmallows, nuts, grapes, raw vegetables, popcorn, and fruit gel snacks have been implicated in choking deaths of preschoolers and toddlers and should be avoided or prepared in a safe manner (Qureshi & Mink, 2003; Shah et al., 2010).

School-aged children, 6 to 12 years old, grow at a slower and steadier rate, with a gradual decline in energy requirements per unit of body weight. The school-aged child gains 3 to 5 kg in weight and 6 cm in height per year until puberty. Despite better appetites and more varied food intake, school-aged children's diets should be carefully assessed for adequate protein and vitamins A and C. School-aged children frequently fail to eat a proper breakfast and have an unsupervised food intake at school. High amounts of fat, sugar, and salt can result from a liberal intake of commercially prepared snack foods.

Inappropriate nutrition may play an important role in childhood obesity. The prevalence of childhood obesity in Canada has increased by 200% to 300% between 1981 and 2001 (Starky, 2005). Data from the 2004 Canadian Community Health Survey (Statistics Canada, 2006) showed that 59% of Canadian children do not consume adequate fruits and vegetables and that these children are significantly more likely to be overweight and obese than those children who consume the recommended amounts of fruits and vegetables. In Prince Edward Island, Aboriginal children were found to not consume the minimum number of fruit and vegetable servings, and less than half of the 55 children in the study sample consumed the minimum number of milk products daily (Taylor et al., 2007). Currently, 18.1% of all Canadian children are classified as overweight and an additional 8.2% as obese (Statistics Canada, 2006). Children who live in Atlantic Canada are twice as likely to be overweight as children in the Prairie Provinces (Willms et al., 2003). In First Nation communities, the prevalence of pediatric and adolescent obesity is much higher (Kuperberg & Evers, 2006).

Considerable health risks are associated with being overweight or obese, including type 2 diabetes, sleep apnea, cardiovascular disease, gallbladder and liver disease, certain types of cancers, hypertension, osteoarthritis, and hypercholesterolemia (Starky, 2005). These diseases and disorders, traditionally limited to adults, are manifesting in Canadian youth (Tremblay, 2003). The prevention and treatment of obesity in childhood and adolescence is a critical public health issue and, ultimately, an important determinant of long-term health. Obesity-prevention strategies recommended by family physicians include initiating obesity prevention during pregnancy, using a family-oriented approach, and encouraging increased physical activity and less television viewing (Plourde, 2006). Evidence suggests also that school interventions may reduce childhood obesity and that the role of parents in this area is critical (Mendelson, 2007).

Nurses who work with children with type 2 diabetes need to be aware of the many implications such a diagnosis can have on a child. Beyond the illness and treatments, these children experience difficult emotions and face issues of identity, autonomy, and belonging—all requiring a sensitive approach. The story in Box 42-2 conveys a nurse's experiences with an adolescent boy who received a diagnosis of diabetes.

Adolescents. During adolescence, physiological age is a better guide to nutritional needs than chronological age.

Energy needs to increase to meet the greater metabolic demands of growth. The daily requirement of protein also increases. Calcium and vitamin D are essential for the rapid bone growth that occurs during adolescence, and girls need a continuous source of iron to replace menstrual blood losses. Boys also need adequate iron for muscle development. In addition to meats and fish, greens, nuts, dried fruits, and whole grains are iron-rich foods (College of Family Physicians of Canada, 2007). Iodine supports increased thyroid activity, so it is important that adolescents use iodized table salt to ensure adequate intake. B-complex vitamins are needed to support heightened metabolic activity.

The adolescent's diet is influenced by many factors other than nutritional needs, including concern about body image and appearance, desire for independence, and fad diets. Nutritional deficiencies may occur in adolescent girls as a result of dieting (Adolescent Health Committee, Canadian Pediatric Society, 2004; reaffirmed 2008) and use of oral contraceptives (Brown et al., 2005). Adolescent girls 14 to 18 years old were found to have inadequate intakes of vitamin B₆, vitamin B₁₂, folate, zinc, iron, magnesium, phosphorus, and vitamin A. Their median calcium, potassium, and fibre intakes were below the adequate intake (AI) level (Health Canada, 2010c). The adolescent boy's diet may be inadequate in vitamin A and magnesium.

Snacks provide approximately 25% of teenagers' total dietary intake. The consumption of fast foods has been associated with excess weight gain, which may be related to the higher energy and fat content of most of these foods. More than 80% of Canadian adolescents report sodium intakes in excess of the upper intake level (UL)—the intake level beyond which the risk of adverse health effects increases (Health Canada, 2010c). Fast-food restaurants also offer larger portions of food, and consumers are eating greater amounts (Wansink et al., 2007). To counteract this trend among adolescents, health promotion initiatives are being implemented in schools to develop supportive environments for healthier eating (e.g., reducing the availability of junk foods in school cafeterias and in vending machines).

The onset of eating disorders such as **anorexia nervosa** or **bulimia nervosa** often occurs during early adolescence when individuals are establishing independence and autonomy. Dieting and weight control are viewed as a defence for feelings of inadequacy or ineffectiveness. In later adolescence, when facing the task of separation-individualization, similar conflicts may arise (Weaver, 2010). Recognition of eating disorders is essential for early intervention (Table 42-2).

Sports and regular exercise necessitate dietary modification to meet the increased energy needs of adolescents. Carbohydrates, both simple and complex, are the main source of energy. Protein needs increase to 1.0 to 1.5 g/kg per day; fat needs do not increase. All athletes need to ingest water before and after exercise to prevent dehydration, especially in hot, humid environments. It is not necessary to supplement the diet with vitamins and minerals, but intake of iron-rich foods is required to prevent anemia (Croll et al., 2006) and calcium with vitamin D to prevent stress fractures (Lappe et al., 2008).

Parents often have more influence over the adolescent diet than they believe they have. Effective strategies include limiting the amount of unhealthy foods kept at home and enhancing the appearance and taste of healthy foods. Making healthy foods more convenient and available and working to change social norms that determine what foods are "cool" are other

BOX 42-2 NURSING STORY

Counselling Children About Nutrition*

Michael was a 13-year-old boy admitted to our pediatric unit with a new diagnosis of type 2 diabetes mellitus. As his nurse, I completed the admission assessment, including height, weight, and baseline vital signs. These values were plotted on a growth chart and it was determined that Michael was also dealing with obesity, which would make nutrition counselling a priority.

I accompanied Michael and his mother to the diabetic clinic to provide ongoing support since we had established a therapeutic relationship. Initially, Michael displayed signs of anger and frustration with his diagnosis; he shared feelings of isolation, being different, and not being accepted by his peers. "Having diabetes will just make things worse. Nobody else has to worry about what they eat or when they eat." Michael needed help acknowledging his feelings and with understanding type 2 diabetes so he could begin to gain control over his health.

Our first goal was for Michael to explore his feelings regarding food. We needed him to think about when, where, and with whom he eats. From there, we would explore his food choices. This was a critical starting point to a process that exposed many difficult emotions for a 13-year-old boy. Irritated and constantly feeling "sick and tired," he was ready to feel better. Michael appreciated that he needed to understand type 2 diabetes and the health challenges that could be incurred if he did not make changes. With the use of illustrations and some relevant YouTube videos, Michael was able to articulate what was happening in his body and what that meant for him.

Our next goal was for Michael to appreciate the value of proper nutrition in controlling blood sugars. Again, using images, Michael was able to understand and describe in his own words the role of protein, fats, and carbohydrates in his body's metabolism. He quickly grasped the significance of counting carbohydrates, concluding that in order to

feel better, he would need to expand his food choices within the recommended guidelines of *Eating Well With Canada's Food Guide*. He further described that one of the strategies he used to fit in with his peers was unhealthy choices such as McCain Pizza Pockets and garlic fingers. He was afraid to change his eating habits as he did not want to appear different from his friends. We explored the potential that making healthy choices could be viewed as being "cool" and discussed his becoming a leader for change among his family and peers.

At this point, we shifted the goal setting to include family initiatives. Michael's mother voiced her frustrations about her busy lifestyle, having two children who refuse to eat fruits and vegetables, and the limitation of a single income. We discussed the importance of fruits and vegetables in relation to blood sugar monitoring and weight. The clinic dietitian encouraged Michael to take a more active role in meal preparation at home to feel more in control of the food being served. The dietitian referred Michael and his mother to "diabetes-friendly" recipes, including fruit smoothies and vegetable wraps, which were an instant success. We talked with Michael about helping his mother with the grocery shopping so they could practise label reading and portion sizes together.

Michael agreed to try these strategies and accepted as a goal to try one new fruit and one new vegetable each day along with incorporating some physical activity into his day. He shared that cutting out screen time would be difficult as he uses that activity for connecting with his peers; we agreed cutting down on screen time would be more appropriate. He began to journal his experience, an activity that included reflections on his food choices and eating environment. At follow-up visits, Michael proudly shared his progress, pleased that he was "beginning to feel more like a 13-year-old—I've even gotten back on my bike!" Michael shared his gratitude for the opportunity to unpack his feelings of isolation and unworthiness and for helping him learn how to take control of his health and wellness.

*By Beverly Gaudet, RN, MN.

ways to promote optimal nutritional health among adolescents (Contento et al., 2006).

Pregnancy occurring within four years of menarche may place the mother and fetus at risk because of the mother's anatomical and physiological immaturity. Malnutrition at the time of conception increases risk to the adolescent and her fetus. Most teenage girls do not want to gain weight, thus counselling adolescent girls on the nutritional needs associated with pregnancy may be difficult; suggestions are better tolerated than rigid directions. The diet of pregnant adolescents is often deficient in calcium, iron, and vitamins A and C. Prenatal vitamin and mineral supplements are recommended.

Young and Middle-Aged Adults. The demands for most nutrients are reduced as the growth period ends. Adults need nutrients for energy, maintenance, and repair, although their energy needs usually decline over the years. Obesity may become a problem as a result of decreased physical exercise, frequent dining out, and the increased ability to afford more luxury foods. Women who use oral contraceptives may need extra vitamins. Iron and calcium intake continues to be important.

Maintaining good oral health is important throughout adulthood. Poor oral hygiene and periodontal disease are potential risk factors for systemic diseases such as bacteremia, endocarditis, cardiopulmonary disease, diabetes mellitus, and for adverse outcomes in pregnancy (WHO, 2008).

Pregnancy. Nutrition during pregnancy influences birth weight and survival chances in infants. Generally, the fetus's needs are met at the expense of the mother. If nutrient sources are not available, both will suffer. The nutritional status of the mother at the time of conception is important because significant aspects of fetal growth and development often occur before pregnancy is suspected.

The energy requirements associated with pregnancy are related to the mother's body weight and activity levels. Pregnant women need 100 kcal per day above the usual allowance during the first trimester and approximately 300 extra calories per day in the second and third trimesters. The additional nutrients should be obtained by including an extra two to three Food Guide Servings from any of the four food groups daily (Health Canada, 2007b). It is recommended that pregnant women have at least 150 g of cooked fish each week to ensure omega-3 fats and other important nutrients and take a multi-vitamin containing 0.4 mg of folic acid and 16 to 20 mg of iron every day (Health Canada, 2011b). Rigid recommendations about weight gain should be avoided because the quality of nutrition during pregnancy is more important than weight gain per se or than the number of kilocalories consumed per day.

Calcium intake is especially critical during the third trimester, when fetal bones are mineralized. Iron may be supplemented to provide for increased maternal blood volume, fetal

► TABLE 42-2

**Potential Assessment
for Eating Disorders****Anorexia Nervosa**

- A. Body weight not maintained over a minimal normal weight for age and height, (e.g., weight loss leading to maintenance of body weight <85% of ideal body weight [IBW]); or failure to make expected weight gain during period of growth, leading to body weight <85% of that expected.
- B. Intense fear of gaining weight or becoming fat, although underweight.
- C. Disturbance in the way in which one's body weight, size, or shape is experienced (e.g., the person claims to "feel fat" even when obviously underweight).
- D. In females, absence of at least three consecutive menstrual cycles when otherwise expected to occur (amenorrhea). (A woman is considered to have amenorrhea if her periods occur only following hormone administration.)

Bulimia Nervosa

- A. Recurrent episodes of binge eating (rapid consumption of a large amount of food in a small period of time).
- B. A feeling of lack of control over eating behaviour during the eating binges.
- C. The person regularly engages in either self-induced vomiting, use of laxatives or diuretics, strict dieting or fasting, or vigorous exercise in order to prevent weight gain.
- D. A minimum average of two binge eating episodes a week for at least three months.

blood storage, and maternal blood loss during delivery. Iodine needs increase 15% to 17% because of increased activity of the thyroid gland. Folic acid intake is particularly important for DNA synthesis and the growth of red blood cells. Inadequate intake may lead to fetal neural tube defects, anencephaly, or maternal megaloblastic anemia (Schlenker & Long, 2011). Health care providers, however, should not advise higher doses of folic acid than prescribed amounts because this may promote the development of colon cancer when preneoplastic cells are present (Kim, 2007; Smith et al., 2008) and the risk of asthma, obesity, and insulin resistance in offspring (Mackerras et al., 2010; Whitrow et al., 2009). Other supplements may also have health risks. For example, vitamin A is essential to maternal and fetal health but is teratogenic (harmful to embryo or fetal growth and development) when consumed in excess (Schlenker & Long, 2011).

Pregnant women should drink at least eight glasses of water daily. They should also avoid artificial sweeteners, alcohol, excessive caffeine, and all drugs not specifically ordered, as these substances pass through the placenta and affect the growing baby. Adequate fluid and fibre intake and moderate exercise help prevent constipation, which is commonly associated with pregnancy in response to the growing uterus, pregnancy hormones, and iron supplementation.

Lactation. Lactating women need 500 kcal per day above the usual allowance because the production of milk increases energy requirements. *Eating Well With Canada's Food Guide* suggests that lactating women ingest the same nutrient levels as

*** BOX 42-3 FOCUS ON OLDER ADULTS****Factors Affecting Nutritional Status**

- Age-related gastrointestinal changes that affect digestion of food and maintenance of nutrition include changes in the teeth and gums, reduced saliva production, atrophy of oral mucosal epithelial cells, increased taste threshold, decreased thirst sensation, reduced gag reflex, and decreased esophageal and colonic peristalsis (Brownie, 2006).
- Presence of other diseases, such as diabetes and cognitive impairments related to delirium, dementia, and depression, increase risk of poor nutrition (Green & Watson, 2006).
- Malnutrition in older adults has multiple causes, such as low income, low educational level, lack of physical functional level to meet activities of daily living, loss, dependency, loneliness, and lack of transportation (Payette & Shatenstein, 2005).
- Nutrition awareness and motivation may be poor: older adults may not read food labels or understand the nutrient value of foods (van Dillen et al., 2008).
- Medications may have adverse effects such as causing anorexia (loss of appetite), xerostomia (severe dryness of the mouth), early satiety, and impaired smell and taste perception. Older adults are more likely to be prescribed medications than younger individuals (Kinosian & Knight-Klimas, 2009).
- Intake of calcium, vitamin D, and phosphorus may be deficient, increasing the risk for osteoporosis. Vitamin B₁₂ may not be synthesized because of lack of intrinsic factor (glycoprotein necessary for the absorption of vitamin B₁₂) in the terminal ileum, decreased lean muscle mass, and lower basic energy expenditure (Masse et al., 2004).

recommended during pregnancy. The need for calcium remains the same as during pregnancy, but lactating women require additional vitamins A and C. Daily intake of water-soluble vitamins (B and C) is needed to ensure adequate levels in breast milk. Fluid intake should be adequate but need not be excessive. Caffeine, alcohol, and drugs are excreted in breast milk and thus should be avoided. It is recommended that nursing be postponed by at least one hour after consuming an alcoholic drink, as it takes an adult woman (55 kg) about 1.25 hours to metabolize the 10 g of alcohol contained in the average drink (Health Canada, 2007a). Tobacco use can decrease the mother's milk production (Einarson & Riordan, 2009).

Older Adults. Adults aged 65 years and older have a decreased need for energy because the metabolic rate slows with age. However, vitamin and mineral requirements remain unchanged from middle adulthood.

Many factors influence the nutritional status of older adults (Box 42-3). Income is significant because for those living on a fixed income, the amount of money available to buy food may be reduced. A large number of older patients benefit from home-delivered or congregate meal services. Health status is another important factor. The older adult may be following a therapeutic diet; have difficulty eating because of physical symptoms, lack of teeth, or dentures; or be at risk for drug-nutrient interactions (Table 42-3). Thirst sensation may diminish, leading to inadequate fluid intake or dehydration (see Chapter 39). Meats may be avoided because of the cost or difficulty to chew. Cheese, eggs, and peanut butter are useful

► TABLE 42-3 Sample Nutrient-Drug Interactions*

Drug	Effect
Analgesic	
Acetaminophen	Decreased drug absorption with food; overdose associated with liver failure
Aspirin	Absorbed directly through stomach; decreased drug absorption with food; decreased folic acid, vitamins C and K, and iron absorption
Antacid	
Aluminum hydroxide	Decreased phosphate absorption
Sodium bicarbonate	Decreased folic acid absorption
Anti-Arrhythmic	
Amiodarone	Taste alteration
Digitalis	Anorexia; decreased renal clearance in older persons
Antibiotic	
Penicillins	Decreased drug absorption with food; taste alteration
Cephalosporin	Decreased vitamin K
Rifampin	Decreased vitamin B ₆ , niacin, vitamin D
Tetracycline	Decreased drug absorption with milk and antacids; decreased nutrient absorption of calcium, riboflavin, vitamin C due to binding
Trimethoprim/ sulfamethoxazole	Decreased folic acid
Anticoagulant	
Coumarin	Acts as antagonist to vitamin K
Anticonvulsant	
Carbamazepine	Increased drug absorption with food
Phenytoin	Decreased calcium absorption; decreased vitamins D and K and folic acid; taste alteration; decreased drug absorption with food
Antidepressant	
Amitriptyline	Appetite stimulant
Clomipramine	Taste alteration; appetite stimulant
Fluoxetine (selected serotonin reuptake inhibitor [SSRI])	Taste alteration; anorexia
Bupropion (monoamine oxidase inhibitor [MAOI])	GI upset and weight loss
Antihypertensive	
Capropril	Taste alteration; anorexia
Hydralazine	Enhanced drug absorption with food; decreased vitamin B ₆
Labetalol	Taste alteration (weight gain for all β -blockers)
Methyldopa	Decreased vitamin B ₁₂ , folic acid, iron
Anti-Inflammatory	
All steroids	Increased appetite and weight; increased folic acid; decreased calcium (osteoporosis with long-term use); promotes gluconeogenesis of protein
Anti-Parkinson	
Levodopa	Taste alteration; decreased vitamin B ₆ ; and decreased drug absorption with food
Antipsychotic	
Chlorpromazine	Increased appetite
Thiothixene	May increase the excretion of riboflavin, which over time decreases the level of riboflavin in the body
Bronchiodilator	
Albuterol sulphate	Appetite stimulant
Theophylline	Anorexia

(2009). 22 Drug-nutrient interactions in the elderly In J. I. Boullata & V. T. Armenti (Eds.), *Handbook of drug-nutrient interactions* (2nd ed., pp. 617-664). New York: Humana Press/Springer.

► TABLE 42-3 Sample Nutrient-Drug Interactions—cont'd

Drug	Effect
Cholesterol Lowering	
Cholestyramine	Decreased fat-soluble vitamins (A, D, E, K); vitamin B ₁₂ ; iron
Diuretic	
Furosemide	Decreased drug absorption with food
Spironolactone	Increased drug absorption with food
Thiazides	Decreased magnesium, zinc, and potassium
Laxative	
Mineral oil	Decreased absorption of fat-soluble vitamins (A, D, E, K), carotene
Platelet Aggregate Inhibitor	
Dipyridamole	Decreased drug absorption with food
Potassium Replacement	
Potassium chloride	Decreased vitamin B ₁₂
Tranquillizer	
Benzodiazepines	Increased appetite

► TABLE 42-4 Religion-Based Dietary Restrictions and Guidelines

Islam	Christianity	Hinduism	Judaism	Church of Jesus Christ of Latter-Day Saints (Mormons)	Seventh-Day Adventists
Pork	Minimal or no alcohol	All meats	Pork	Alcohol	Pork
Alcohol		Alcohol	Predatory fowl	Tobacco	Shellfish
Caffeine	Holy-day observances	Onions	Shellfish (eat only fish with scales)	Caffeine	Alcohol
Emulsifiers made from animal fats, especially margarines	may restrict meat	Garlic	Rare meats	Limit meat	Vegetarian diet encouraged
Ramadan fasting sunrise to sunset for one month			Blood (blood sausage, etc.)		
Ritualized methods of animal slaughter required for meat ingestion			Do not mix milk or dairy products with meat dishes		
			Must adhere to kosher food preparation methods		
			24 hours of fasting on Yom Kippur, a day of atonement		
			No leavened bread eaten during Passover (eight days)		
			No cooking on the Sabbath (Saturday)		

high-protein alternatives. Cream soups and meat-based vegetable soups are nutrient-dense sources of protein; yet, commercial soups and packaged meats contain a high salt content. Milk continues to be an important food for older adults to protect against osteoporosis (a decrease of bone-mass density). Although research has shown that older men lag behind women by approximately a decade in developing osteoporosis, screening and treatment are necessary for both older men and women (Schlenker & Long, 2011). The diets of older adults should contain choices from all food groups and may require a vitamin and mineral supplement.

Alternative Food Patterns

Many people follow special patterns of food intake that are based on religion (Table 42-4), cultural background (Box 42-4)

ethics, health beliefs, personal preference, or concern for the efficient use of land to produce food. Such special diets are not necessarily more or less nutritious than diets based on *Eating Well With Canada's Food Guide* or other nutritional guidelines because good nutrition depends on a balanced intake of all required nutrients.

Vegetarian Diet. Vegetarianism is the consumption of a diet consisting predominantly of plant foods. Vegetarians may be ovo-lacto vegetarians (avoid meat, fish, and poultry but eat eggs and milk), lacto-vegetarians (drink milk but avoid eggs), or vegans (consume only plant foods). Vegetarian diets often have lower levels of total fat, saturated fat, and cholesterol than many meat-based diets, and higher intakes of fibre, magnesium, potassium, folate, and antioxidants such as vitamins C and E. Because of this, vegetarian diets may lead to

* BOX 42-4 CULTURAL ASPECTS OF CARE

Nutrition

Food patterns developed as a child, through habits and culture, interact to influence food intake. Culture also influences the meaning of food not related to nutrition. Eating is associated with sentiments and feelings such as "good" and "bad." For example, children are often rewarded for "being good" with a treat such as candy. They then associate candy with "being good."

The incidence of lactose intolerance around the world occurs in the following ethnic or racial groups: Asian-Pacific, African and African American, Native American, Mexican American, Middle Eastern, and Whites. This condition affects nutrient absorption, and calcium deficiency results. The theory of "hot" and "cold" foods predominates in many cultures. The foundation of the theory is that to keep harmony with nature, one must balance "cold," "hot," "wet," and "dry." Some cultures believe hot characterizes warmth, strength, and reassurance, whereas cold represents menace and weakness. Classification of a food has nothing to do with spiciness but is a symbolic representation of temperature.

Source: Adapted from Giger, J. N., & Davidhizar, R. E. (2004). *Transcultural nursing: assessment and intervention* (3rd ed.). St Louis, MO: Mosby.

Implications for Practice

- Identify the meaning that certain types of food have for each patient.
- Lactose and other food intolerances unique to specific cultures require diet adaptation to meet nutrient, mineral, and vitamin daily-intake requirements.
- In some cultures, specific conditions require hot foods. Menstruation, cancer, pneumonia, earache, colds, paralysis, headache, and rheumatism are "cold" illnesses requiring hot foods (e.g., rice, grain cereals, alcohol, beef, lamb, chili peppers, chocolate, cheese, temperate-zone fruits, eggs, peas, goat's milk, corn husks, oils, peanuts, onions, pork, radishes, tamales).
- Other conditions, such as pregnancy, fever, infections, diarrhea, rashes, ulcers, liver problems, constipation, kidney problems, and sore throats, are "hot" conditions requiring cold foods (e.g., beans, citrus fruits, tropical fruits, dairy products, most fresh vegetables, honey, raisins, chicken, fish, and goat meat).

lower blood pressure, improved cholesterol levels, healthier weight, and less incidence of type 2 diabetes, all of which can reduce the risk of heart disease and stroke (Barnard et al., 2009; Heart and Stroke Foundation, 2008).

Dietitians of Canada and the American Dietetic Association further maintain that appropriately planned vegetarian diets can help prevent prostate and colon cancer (Mangels et al., 2003). Yet, knowledge related to complementary use of complete and incomplete proteins, food sources of vitamin B₁₂ (e.g., fortified breakfast cereal and soy milk), and nondairy sources of calcium is necessary (Messina et al., 2003). Vegan, Zen macrobiotic (consisting primarily of brown rice, other grains, and herb teas), and fruitarian (consisting of only fruit, nuts, honey, and olive oil) diets can be nutrient poor and can result in malnutrition. Children who follow a vegetarian diet are especially at risk for protein and vitamin deficiencies such as vitamin B₁₂ (Mangels et al., 2003; Stabler & Allen, 2004). Canadian adolescent girls and women of reproductive age who are vegetarian are at greater risk for low iron stores because diets high in plant foods contain dietary iron inhibitors (Cooper et al., 2006). Vegetarian athletes at risk for low intakes of energy, protein, fat, and key micronutrients such as iron, calcium, vitamin D, riboflavin, zinc, and vitamin B₁₂ may need consultation with a sports dietitian (Rodriguez et al., 2009).

Vegetarian diets may include:

1. Semi or partial-vegetarian: May eat some milk products, eggs, poultry, and fish while primarily consuming plant-based foods
2. Pesco-vegetarian: May eat fish, eggs, dairy products, grains, vegetables, fruits, legumes, seeds, nuts while avoiding meat and poultry
3. Lacto-ovo-vegetarian: Eating eggs, dairy products, grains, vegetables, fruits, legumes, seeds, nuts while avoiding meat, poultry, and fish
4. Lacto-vegetarian: Eating dairy products, grains, vegetables, fruits, legumes, seeds, nuts while avoiding meat, fish, poultry, and eggs
5. Vegan: Eating grains, vegetables, fruits, legumes, seeds, nuts while avoiding meat, fish, poultry, eggs, dairy, and honey

In general, plant-based diets are low in saturated fat and cholesterol and high in fibre, folate, vitamin C and E, potassium, and magnesium. Health Canada (2011) instructs those who follow vegetarian diets to ensure adequate nutrient intake by choosing "either milk or fortified soy beverages as part of the Milk and Alternatives food group" and various meat alternatives such as "beans, lentils, eggs, tofu, soy-based meat substitutes, nuts, nut butters and seeds from the Meat and Alternatives food group."

Calcium deserves special attention in vegetarian food guidelines because women practicing vegan and even lacto-ovo-vegetarian diets may have inadequate calcium intakes (Messina, Melina & Mangels, 2003). A major criticism of using Canada's Food Guide for vegetarian diet planning is that soymilk is the only vegan milk alternative mentioned. In addition to fortified soy drinks and products (e.g., soy yogurts, tofu), good vegan sources of calcium include navy beans and white beans; nuts and nut products like almonds and almond butter; seeds like sesame seeds and their butter (tahini); blackstrap molasses; vegetables such as bok choy, okra, collard greens and turnip greens, and fruits like figs and fortified orange juice (Dietitians of Canada, 2010).

The healthy vegan diet must also ensure adequate protein, iron, zinc, and vitamins D and B₁₂ (Amit et al., 2010). As a general rule, our bodies need approximately 0.8 grams of protein for every kilogram of body weight. This means that a person weighing 60 kg requires approximately (60 kg × 0.8) or 48 grams of protein daily. The lower digestibility of plant proteins may however necessitate increased protein intake for infants and children (Messina & Mangels, 2001). Sources of protein include soy and soy products; meat alternatives (e.g., textured vegetable protein and veggie burgers); dried beans (e.g., kidney, black and white beans), peas (e.g., chickpeas and black-eyed peas), and lentils (e.g., red, brown and green lentils); and grains, nuts and seeds (Dietitians of Canada, 2010). For children under the age of five, certain high-protein foods such as whole nuts or seeds are to be avoided as they represent a choking risk (Ministry of Health, 2012). A range of plant protein products are needed because particular amino

acids that are abundant in some foods may be limited in other foods and vice versa. By consuming a wide variety of foods, the amino acids “complement” each other to provide the essential amino acids in proper balance.

Vegan iron sources include the above protein sources, specifically firm or extra firm tofu, pinto and adzuki beans, almonds, and sesame seeds (Dietitians of Canada, 2010). Iron is additionally found in fruits such as prunes, raisins and apricots; dark green vegetables such as collards, okra and bok choy; and blackstrap molasses (Dietitians of Canada, 2010). The form of iron present in foods of plant origin is not well absorbed by the body; its rate of absorption can be increased up to six times by incorporating foods high in vitamin C (University of Western Ontario Hospitality Services). Zinc is found in soy products; dried beans, peas and lentils; nuts such as peanuts, pecans, and cashews and seeds such as pumpkin and flax; whole grains and fortified cereals.

Unsupplemented vegan diets do not provide Vitamin B12. It is recommended that all people over the age of 50, regardless of type of diet, take vitamin B₁₂ in supplements and fortified foods (e.g., fortified nondairy milks, fortified meat alternatives, and breakfast cereals). Vitamin B₁₂ is also contained in Red Star nutritional yeast, the only brand of nutritional yeast in Canada fortified with vitamin B₁₂. It has a similar flavour to cheese and can be sprinkled on top of casseroles and in soups. Vegan diets require a source of vitamin D when sun exposure is insufficient. Many fortified nondairy milks and breakfast cereals provide vitamin D, although the form used to fortify cereals is often not vegan (Dietitians of Canada, 2010). Good sources of vitamin D include fortified soy and other fortified non-dairy drinks and soft margarines. Vitamin D supplements may be used. There is no mention of vegetarian sources of omega-3 in Canada’s Food Guide. Omega-3 fats are found in oils (canola, flax seed, walnut and soybean); ground flax seed; and soybeans, tofu, and walnuts.

People over the age of 50 need additional calcium, vitamin D, and B₁₂. They should include three servings of fortified beverage each day to help meet calcium needs. It is also recommended that they take 400 IU of vitamin D each day from a supplement. They should get vitamin B12 from fortified foods or a supplement. A daily multivitamin-mineral supplement will help provide these extra vitamins and minerals (Dietitians of Canada, 2010).

Critical Thinking

Critical thinking requires the gathering and synthesizing of knowledge, experience, information from patients that is gained through intellectual and professional standards and attitudes of open-mindedness, respect for patient autonomy, and confidence. Clinical judgements involve the anticipation of the required information, analysis of the data, and openness to new ideas and multiple perspectives when making decisions regarding patient care. Critical thinking is thus a dynamic process. During assessment (Figure 42-4), all elements that contribute to the rendering of appropriate nursing diagnoses are considered.

When assessing nutrition, the nurse must integrate knowledge from nursing and other disciplines, previous experiences, information gathered from patients and families about food preferences, clinical observations, and dietary history. Professional standards, such as the DRIs and *Eating Well With Canada’s Food Guide* (Health Canada, 2007b), provide guidelines for

Figure 42-4 Critical thinking model for nutrition assessment.

assessing and maintaining patient nutritional status. Other professional standards from the Heart and Stroke Foundation of Canada, the Canadian Cancer Society, Canadian Society for Clinical Nutrition, and the Canadian Dietetic Association are available. These standards are research based and regularly updated to enhance optimal care.

Nursing Process and Nutrition

Nurses are in an excellent position to recognize signs of poor nutrition and take steps to initiate change. Close contact with patients and their families enables nurses to make observations about physical status, food intake, weight changes, and responses to therapy.

◆ Assessment

Early recognition of malnourished or at-risk patients has a strong, positive influence on both short- and long-term health outcomes. Studies have identified 20% to 50% of adult patients as being nutritionally at risk upon hospital admission and that such malnutrition increases hospital costs (Amarat et al., 2007; Kubrak & Jensen, 2007). Other studies have shown a relationship between malnutrition and adverse outcomes, including

Figure 42-5 Sample items from SCREEN for nutrition screening of seniors. **Source:** From Keller, H. H., Hedley, M. R., & Brownlee, S. W. (2000). The development of seniors in the community: Risk evaluation for eating and nutrition (SCREEN). *Canadian Journal of Dietetic Practice and Research*, 61(2), 72. SCREEN©. Seniors in the Community: Risk Evaluation for Eating and Nutrition. *Note:* This is only a sample from the tool and cannot be used on its own.

mortality (Stratton & Elia, 2006; Stratton et al., 2006). Moreover, the prevalence of malnutrition among special patient populations (e.g., oncology patients) may range as high as 90% (Kubrak & Jensen, 2007) and is associated with the interrelations between disease severity, disability, treatment, and self-care practices. Clearly, accurate assessment and recording of nutritional status is necessary to help patients make significant differences in their health and quality of life.

Nutritional screening is part of an initial assessment that involves identification of patients who are either malnourished or at risk of malnourishment (Green & Watson, 2005). The SCREEN (Figure 42-5) is a nutrition-risk screening index that consists of 15 questions about weight change, food and fluid intake, and risk factors associated with food and fluid intake. Five responses to questions are possible, with item scores ranging from 0 to 4. Low scores (<50) indicate increased nutritional risk (Beath & Keller, 2007).

Nutritional assessment goes beyond nutritional screening and involves five major areas: anthropometry, laboratory tests, dietary and health history, clinical observation and physical examination, and patient expectations. Assess nutritional

status when a condition exists that interferes with the patient's ability to ingest, digest, or absorb adequate nutrition. No single area or measurement accurately determines nutritional status, and a patient's personal and social health context needs to be considered.

Anthropometry

Anthropometry is a measurement system of the size and makeup of the body. Height and weight are obtained for each patient admission to any health care setting. If height cannot be measured with the patient standing, position the patient lying flat in bed as straight as possible with arms folded on the chest, and measure the patient lengthwise. If possible, the patient should be weighed at the same time each day, on the same scale, and with the same apparel. Serial measures over time provide more useful information than one-time measurement. An **ideal body weight (IBW)** provides an estimate of what a person should weigh. Rapid weight gain usually reflects fluid shifts. Five hundred mL of fluid equals 0.45 kg. For example, for a patient with renal failure or heart failure, a weight increase of 0.9 kg is significant, as it may indicate that the patient has retained a litre of fluid. Recent weight changes should be documented.

Body mass index (BMI) measures weight corrected for height and serves as an alternative to traditional height-weight relationships.

Calculation of BMI is achieved by dividing the patient's weight in kilograms by height in metres squared: $\text{Weight (kg)} / \text{Height}^2 (\text{m}^2)$. The BMI nomogram is available on Health Canada's Web site at http://www.hc-sc.gc.ca/fn-an/nutrition/weights-poids/guide-ld-adult/bmi_chart_java-graph_imc_java-eng.php. A BMI measuring between 25 and 30 indicates overweight, and greater than 30 defines obesity (Health Canada, 2003a). The BMI is a valid measurement of weight in relation to health; however, it is not recommended for use as the sole measurement of body composition or level of fitness because it does not differentiate between excess fat and muscle or bone and does not consider age, gender, or ethnicity (Health Canada, 2003a; Scheier, 2004). Care must be taken when interpreting overweight and obesity results for Canadian child obesity, as cutoff points different from adult cutoffs are used (He & Beynon, 2006; Statistics Canada, 2010c).

Heart and Stroke Foundation research indicates that for most people, the **waist circumference (WC)** measurement may be used to determine health risk. Overweight people who carry excess pounds around the waist are at greater risk of heart disease and stroke than those who carry it on their hips, thighs, and buttocks. The WC is measured at the part of the trunk located midway between the lower costal margin (bottom of lower rib) and the iliac crest (top of pelvic bone) while the person is standing, with feet somewhat apart. The person doing the measuring should stand beside the individual and fit the tape snugly, without compressing any underlying soft tissues. The circumference should be measured to the nearest 0.5 cm, at the end of a normal expiration. In men, a WC of 102 cm (40 inches) or greater places them at significant increased risk for heart disease and stroke. In women, this measurement is 88 cm (35 inches) or more (Health Canada, 2003a; Heart and Stroke Foundation, 2008).

Laboratory and Biochemical Tests

No single laboratory or biochemical test can be used to diagnose malnutrition. Factors that may alter test results include

fluid balance, liver function, kidney function, and the presence of disease. Common laboratory tests used to study nutritional status include measures of plasma proteins such as albumin, transferrin, prealbumin, retinol-binding protein, total iron-binding capacity, and hemoglobin. After feeding, the response time for changes in these proteins ranges from hours to weeks. The metabolic half-life of albumin is 21 days; transferrin, 7 days; prealbumin, 2 days; and retinol-binding protein, 12 hours. This range demonstrates why albumin level, for example, is not an accurate short-term indicator of serum protein status (Corbett, 2008). Serum albumin levels are affected by hydration; hemorrhage; renal or hepatic disease; acquired immune deficiency syndrome (AIDS); high-output drainage of wounds, drains, burns, or the gut; steroid administration; albumin infusions; age; pregnancy; and trauma, burns, stress, or surgery. Albumin level is a better indicator of chronic illnesses, whereas prealbumin level is a preferred indicator of acute conditions.

Nitrogen balance is important to establish serum protein status (see “Proteins” section). Nitrogen intake is calculated by dividing 6.25 into the total grams of protein ingested in a 24-hour period (Schlenker & Long, 2011). The output of nitrogen is established through laboratory analysis of a 24-hour urinary urea nitrogen level.

For patients with diarrhea or fistula drainage, a further addition of 2 to 4 g of nitrogen output is estimated. Nitrogen balance is found by subtracting the nitrogen output from the nitrogen intake. A positive (more nitrogen taken in than put out) 2 to 3 g nitrogen balance is ideal for anabolism. In contrast, negative (more nitrogen put out than taken in) nitrogen balance is present when catabolic states exist, such as in starvation or physiological stress.

Dietary History and Health History

Gather information about the patient’s illness or activity level to determine energy needs and compare that information with

food intake. Nursing assessment of nutrition also includes health status; age; cultural background (see Box 42-4); religious food patterns (see Table 42-4); socioeconomic status; personal food preferences; psychological factors; use of alcohol or illegal drugs; use of vitamin, mineral, or herbal supplements and prescription or over-the-counter drugs; and the patient’s general nutrition knowledge. Polypharmacy, multiple concurrent medication use, is a significant predictor of nutritional status in older adults and requires careful assessment (Chen et al., 2007).

In addition to the general nursing health history, a diet history is needed to assess the patient’s needs (Table 42-5). The dietary history focuses on the patient’s habitual intake of foods and liquids, as well as information about preferences, ability to obtain food, and allergies. Eliciting the diet and health history requires careful and respectful exploration of the patient’s perceived health status to identify any hidden areas of concern such as contained in the story (Box 42-5) of one nurse’s personal experience with celiac disease, a condition that damages the villi found within the lining of the small intestine, preventing absorption of nutrients important for staying healthy. The damage is due to a reaction to eating gluten, which is found in wheat, barley, rye, and possibly oats (Green & Cellier, 2007; Smith & Goodfellow, 2011).

Outpatient patients may keep a three- to seven-day food diary, which will enable more accurate calculation of nutritional intake and comparison to *Eating Well With Canada’s Food Guide* and DRIs to see if dietary habits are adequate. Culturally sensitive food-frequency questionnaires may also be used to establish patterns over time.

Clinical Observation and Physical Examination

Clinical observation is key to nutritional assessment. Because improper nutrition affects all body systems, observe the patient for signs of nutritional alterations during physical assessment (see Chapter 31). When the general physical assessment of the

BOX 42-5 NURSING STORY

A Life Changed*

Celiac disease (celiac) always seemed like a pretty straightforward disease to me: people with it who eat gluten have vomiting, diarrhea, and weight loss. As far as I was concerned, I knew the signs and symptoms of celiac, and I have three cousins who have it. What I didn’t know were the other, less obvious symptoms of celiac—ones that I had.

I was about to turn 30 when I went for routine allergy testing. I had stopped taking antihistamines four years earlier during pregnancy and wanted to see if I had “outgrown” my environmental allergies. The nurse interviewed me before the testing to ensure that she would test for the right allergens. When she asked me if I had any food allergies, my response was to laugh out loud. As an overweight woman, I explained that the only thing I wasn’t allergic to was food. The nurse invited me to share my medical history or any health issues I was having. She listened as I explained my past experience of postpartum depression and iron-deficiency anemia and my current difficulty getting pregnant again, frequent heartburn, and irritable bowel syndrome. When asked about my family history, I mentioned my cousins with celiac but added I didn’t have that. The nurse said she would test me for wheat allergy, just to make sure. I didn’t know it at the time, but because of

her experience as a nurse working at an allergy clinical, she identified symptoms commonly experienced by those with celiac—symptoms that even though I was a nurse myself I didn’t know to look for because I had not taken care of patients with celiac. I was shocked that day to find out that I had a wheat allergy. The follow-up blood testing ordered by the physician as well as the subsequent upper endoscopy performed to sample a piece of tissue (biopsy) from the first part of the small intestine (duodenum) confirmed the diagnosis. My life hasn’t been the same since. It’s been better!

Although transitioning to eating a gluten-free diet has been challenging, it’s been worth it. I learned to read food and medication labels carefully to look for hidden sources of grains and ingredients related to them. Because wheat and barley grains are common in the Canadian diet, sticking with this diet is difficult. I also got help from a registered dietitian who specialized in celiac disease and the gluten-free diet.

The nurse caring for me that day changed my life. In the brief time that we spent together, she was able to identify the one thing that was affecting my life in every way. By listening to my story and using her nursing expertise to connect her knowledge and experiences with mine, she was able to help me live a whole life. For that I will forever be grateful.

*By Daphne Kennedy, BN, RN, MN student.

► **TABLE 42-5** Obtaining a Dietary History (Acronym: FASTCHECK)

Components of a Dietary History	Areas to Assess and Questions to Ask
Food Practices	
Number, type, and location of meals eaten per day	How many meals do you eat? At what times do you usually eat? Are these scheduled meals or snacks? Where do you usually eat meals and snacks? With whom?
Food preferences	What types of food do you like?
Food-preparation practices	Who prepares the food?
Food-purchasing practices	Who purchases the food?
Allergies	Are you allergic to any foods? Specify these foods. What happens when you eat these foods? Specify the type of allergic response (e.g., hives, itching, anaphylaxis). What is done to treat allergies (e.g., EpiPen, oral antihistamines)?
Symptoms	
Indigestion, heartburn, gas, alterations in taste	What foods cause indigestion, gas, or heartburn? Does this occur each time you eat the food? Have you noticed any changes in taste? Did these changes occur with medications or following an illness?
Relief practices	What relieves the symptoms?
Twenty-Four Hour Recall	
To conduct the 24-hour diet recall (Wiehl, 1942), ask the patient to describe every item of food and drink ingested in a 24-hour period. The easiest time period to recall is from the time one awakens to the time one goes to bed again.	
a. Using open-ended questions and systematic repetition, ask, "When you first woke up yesterday, what was the first thing you put in your mouth?" "How much of it did you have?" "What time was that?" "What did you eat or drink next?" Do not ask about specific meals. Do ask for foods and drinks between any meals and at bedtime.	
b. Ask for specific types of foods and drinks: for example, "What kind of milk—whole, fat-free?" What kind of rice—brown, white?"	
c. Record time and amounts of all food eaten.	
d. Find out about methods of preparation (e.g., salt, fat) and ingredients in mixed dishes.	
e. Record intake of drinks to assess the adequacy of fluid intake.	
f. Determine if this intake is typical of most days.	
g. Record type and amount of alcoholic beverages and nonfood items consumed. Document servings consumed under "Other foods and beverages."	
After all the information for the diet history is collected, evaluate the 24-hour recall by	
a. Counting and recording the number of servings eaten for each food group	
b. Compare servings eaten to recommended daily servings appropriate for the age and sex of the patient	
Be aware that an individual may have difficulty estimating portion sizes and remembering everything, that 24 hours may not be representative of diet, and that the individual may feel pressure to say what is perceived as desired.	
Chewing and Swallowing	Do you wear dentures? Full or partial? Orthodontic devices? Are the dentures or devices comfortable? Assess the condition of the patient's teeth. Do you experience mouth pain or sores (e.g., cold sores, canker sores)? Do you have difficulty swallowing? Do you cough or gag when you swallow?
Hunger	
Appetite	Have you had a change in appetite? Have you noticed a change in weight?
Satiety	Was this change an anticipated change (e.g., were you following a weight-reduction diet)? Do you stop eating when feeling full? Do you pick at food between meals or eat substantially before bedtime?
Elimination Patterns	How often do you have bowel movements? Do you experience diarrhea with meals or specific foods? If yes, how do you manage the diarrhea? Do you experience constipation? If yes, how do you manage it?
Chemical Substances	
Medication use	What medications do you take?
Over-the-counter substances	Do you take any over-the-counter medications that your doctor does not prescribe? If yes, specify them.
Supplements	Describe any nutritional or herbal supplements you use.
Knowledge	Do you believe your current diet is adequate for meeting your energy needs? If not, what would you like to change?

► TABLE 42-6 Clinical Signs of Nutritional Status

Body Area	Signs of Good Nutrition	Signs of Poor Nutrition
General appearance	Alert; responsive	Listless, apathetic, cachectic appearance
Weight	Weight appropriate for height, age, body build	Obese or underweight appearance (special concern for underweight)
Posture	Erect posture; straight arms and legs	Sagging shoulders; sunken chest; humped back
Muscles	Well-developed, firm muscles; good tone; some fat under skin	Flaccid appearance, poor tone, underdeveloped tone; tenderness; edema; wasted appearance; inability to walk properly
Nervous system control	Good attention span; lack of irritability or restlessness; normal reflexes; psychological stability	Inattention; irritability; confusion; burning and tingling of hands and feet (paresthesia); loss of position and vibratory sense; weakness and tenderness of muscles (may result in inability to walk); decrease or loss of ankle and knee reflexes; absent vibratory sense
Gastrointestinal function	Good appetite and digestion; normal regular elimination; no palpable organs or masses	Anorexia; indigestion; constipation or diarrhea; liver or spleen enlargement
Cardiovascular function	Normal heart rate and rhythm; lack of murmurs; normal blood pressure for age	Rapid heart rate (above 100 beats/minute), enlarged heart; abnormal rhythm; elevated blood pressure
General vitality	Endurance; energy; good sleep habits; vigorous appearance	Easily fatigued; lack of energy; falling asleep easily; tired and apathetic appearance
Hair	Shiny, lustrous appearance; firmness; strands not easily plucked; healthy scalp	Stringy, dull, brittle, dry, thin, and sparse, depigmented appearance; strands that can be easily plucked
Skin (general)	Smooth and slightly moist skin with good colour	Rough, dry, scaly, pale, pigmented, irritated appearance; bruises; petechiae; subcutaneous fat loss
Face and neck	Uniform colour; smooth, pink, healthy appearance; lack of swelling	Greasy, discoloured, scaly, swollen appearance; dark skin over cheeks and under eyes; lumpiness or flakiness of skin around nose and mouth
Lips	Smoothness; good colour; moist (not chapped or swollen) appearance	Dry, scaly, swollen appearance; redness and swelling (cheilosis); angular lesions at corners of mouth; fissures or scars (stomatitis)
Mouth, oral membranes	Reddish pink, intact mucous membranes in oral cavity	Swollen, boggy oral mucous membranes
Gums	Pink; healthy appearance; lack of swelling or bleeding	Spongy gums that bleed easily; marginal redness, inflammation; receding gums
Tongue	Pink or deep reddish colour; lack of swelling; smoothness, presence of surface papillae; lack of lesions	Swelling, scarlet, and raw appearance; magenta colour, beefiness (glossitis); hyperemic and hypertrophic papillae; atrophic papillae
Teeth	Lack of cavities and pain; bright, straight appearance; lack of crowding; well-shaped jaw; clean appearance with no discolouration	Unfilled caries; absent teeth; worn surfaces; mottling (fluorosis); malpositioned appearance
Eyes	Bright, clear, shiny appearance; lack of sores at corner of membranes; eyelids moist and healthy pink colour; prominent blood vessels or lack of mound of tissue or sclera; lack of fatigue circles beneath eyes	Pale eye membranes (pale conjunctivae); redness of membrane (conjunctival infection); dryness; signs of infection; buildup of keratin debris in the conjunctiva (Bitot's spots), redness and fissuring of eyelid corners (angular palpebritis); dryness of eye membrane (conjunctival xerosis); dull appearance of cornea (corneal xerosis); soft cornea (keratomalacia)
Neck (glands)	Lack of enlargement	Thyroid enlargement
Nails	Firm, pink appearance	Spoon shape (koilonychia); brittleness; ridges
Legs, feet	Lack of tenderness, weakness, or swelling; good colour	Edema; tender calves; tingling; weakness
Skeleton	Lack of malformation	Bowlegs; knock knees; chest deformity at diaphragm; prominent scapulae and ribs

Source: Schlenker, E. D., & Long, S. (2007). *Williams' essentials of nutrition and diet therapy* (9th ed., p. 12). St Louis, MO: Mosby.

body systems is complete, pertinent areas can be rechecked to evaluate the patient's nutritional status. The clinical signs of nutritional status (Table 42-6) provide guidelines for observation during physical assessment.

Assess for aspiration (choking) risk and dysphagia (difficulty when swallowing). Those at risk of aspiration may have decreased levels of alertness, decreased gag or cough reflexes, difficulty managing saliva, or a wet, gurgling voice. The

warning signs of dysphagia include coughing during eating; change in voice tone or quality after swallowing; abnormal movements of the mouth, tongue, or lips; slow, weak, imprecise, inconsistent, or uncoordinated speech; abnormal gag reflex; delayed swallowing; incomplete oral clearance or pocketing of food or medications; and regurgitation. In Canada, approximately half of all new stroke patients older than 65 years of age live with dysphagia for months after the stroke.

Patients with dysphagia often do not show overt signs such as coughing when food enters the airway. “Silent aspiration” occurs in those with decreased sensation related to neurological problems (Garon et al., 2009; Ramsey et al., 2005) and accounts for most of the aspiration in patients with dysphagia following stroke (Westergreen, 2006). Early detection of dysphagia improves outcomes such as malnutrition, dehydration, pulmonary compromise, mortality, length of hospital stay, and overall health care expenditures (Heart and Stroke Foundation of Ontario, 2006).

The Canadian Stroke Network (2010, 2011) recommends early screening of all stroke patients, using a simple, valid, reliable formal dysphagia protocol before initiating oral intake of medications, fluids, or food in order to identify swallowing problems, help initiate referrals for more in-depth assessment, and significantly decrease risk of aspiration pneumonia. Nurses should implement aspiration precautions (Skill 42-1),

and refer patients at risk of malnutrition, including those with dysphagia, to a dietitian for nutrition assessment and ongoing management.

Patient Expectations

Because patients rely on nurses and other health care providers to identify problems, nurses must be knowledgeable about nutrition and nutritional screening, assessment, and referral to meet patient expectations and needs.

❖Nursing Diagnosis

Assessment enables determination of any actual or potential nutrition problems (Box 42-6). A problem may occur when overall intake is significantly decreased or increased, or when one or more nutrients are not ingested, completely digested, or completely absorbed. Specific diagnoses are related to the

► SKILL 42-1 Aspiration Precautions

Delegation Considerations

The assessment of aspiration risk and determination of positioning cannot be delegated to unregulated care providers (UCPs). However, UCPs may feed patients after receiving instructions about aspiration precautions. It is important to instruct UCPs about the following:

- Appropriate patient positioning to decrease aspiration risk
- Reporting of any onset of coughing, gagging, or pocketing of food

Procedure

STEPS

1. Give patients who are not alert within the first 24 hours post-stroke nothing by mouth (NPO) and monitor closely.
2. Assess patients at increased risk of aspiration for signs and symptoms of dysphagia (e.g., cough, change in voice after swallowing).
3. Ask patient about any difficulties with chewing or swallowing foods with different textures.
4. Ensure the clinical bedside screening trial is conducted by a speech language pathologist (SLP) or appropriately trained specialist.
5. Elevate head of patient's bed so that hips are flexed at a 90-degree angle and head is flexed slightly forward, or help patient to the same position in a chair.
6. The clinical bedside screening trial involves giving 5 to 10 mL of water, and if that is well tolerated, it is followed by a small cup (50 mL) of water.
7. For a patient who may feed self, explain that you are initially observing while the patient eats:
 - A. Observe patient consume various consistencies of food and liquids, watching for signs of dysphagia.
 - B. Note at the end of the meal if patient becomes tired.
 - C. Report signs and symptoms of dysphagia.
- D. Place identification on patient's record indicating that dysphagia is present.
8. For patients who require supervision or assistance with eating because dysphagia and risk of aspiration have been identified, explain that you will assist them with their meal:

Equipment

- Chair or electric bed (to allow patient to sit upright)
- Thickening agents as needed (commercial prethickened products or commercial thickening agent)
- Tongue blade
- Penlight

RATIONALE

- Risk of aspiration is high (Canadian Stroke Network, 2006)
- Patients at risk include those who have COPD or neurological or neuromuscular diseases and those who have had trauma to or surgical procedures of the oral cavity or throat.
- Certain types of food are more easily aspirated.
- The SLP is qualified to assess and to advise on the safety of the patient's swallowing ability and the consistency of diet and fluids.
- Reduces risk of aspiration (Metheny, 2004).
- Patients indicating dysphagia or pulmonary aspiration are to receive a full clinical assessment of their swallowing ability by a trained team member.
- Increases patient cooperation.
- Referral to a dietitian and SLP is appropriate if patient has difficulty with a particular consistency.
- Fatigue increases risk of aspiration.
- Signs or symptoms indicate the need for further evaluation of swallowing by SLP in collaboration with radiology department, such as a fluoroscopic swallow study (Garon et al., 2009). A significant number of individuals who aspirate do not exhibit signs and symptoms of dysphagia (Logeman et al., 2008).
- Alerts the health care team to the problem and helps the team to develop and implement an individualized plan of care (Nowlin, 2006).
- Increases patient comfort.

► SKILL 42-1 Aspiration Precautions—cont'd**video**

- A. Perform hand hygiene.
 - B. As ordered or recommended by the feeding/swallowing team, add thickener to thin liquids to create the consistency of nectar, honey, or pudding.
 - C. Place 1/2 (2.5 g) to 1 teaspoon (5 g) of food on unaffected side of the mouth, allowing utensil to touch the mouth or tongue.
 - D. Place hand on throat to gently palpate swallowing event as it occurs. Swallowing twice is often necessary to clear the pharynx.
 - E. Provide verbal coaching and positive reinforcement while feeding patient.
 - Feel the food in your mouth.
 - Chew and taste the food.
 - Raise your tongue to the roof of your mouth.
 - Think about swallowing.
 - Close your mouth and swallow.
 - Swallow again.
 - Cough to clear airway.
 - F. Observe for coughing, choking, gagging, and drooling of food; suction airway as necessary.
 - G. Provide rest periods as necessary during meal to avoid rushed or forced feeding.
 - H. Using a penlight and tongue blade, gently inspect patient's oral cavity during and after the meal to detect pockets of food.
 - I. Ask patient to remain sitting upright for at least 30 minutes after the meal.
 - J. Help patient to perform hand hygiene and mouth care.
 - K. Record intake and report any observations indicative of feeding and swallowing difficulties.
 - L. Ensure return of patient's tray to appropriate place, and perform hand hygiene.
 - 9. Weigh patient weekly at the same time on the same scale.
- Reduces transmission of microorganisms.
 - Thin liquids such as water and fruit juice are difficult to control in the mouth and are more easily aspirated (Canadian Stroke Network, 2010). It is essential to follow the team's determination for consistency because best practices have not as yet been established and individual clinicians may lack training (Campbell-Taylor, 2008). In one Canadian study, dementia and Parkinson's disease patients aspirated less often with honey-thickened liquids than with nectar-thickened liquids and chin-down posture (Logemann et al., 2008). Future investigation is needed to determine whether chin-down posture combined with honey or nectar-thickened liquid better prevents aspiration than either intervention independently (Robbins et al., 2008).
 - Provides patient with tactile cues to begin eating.
 - Helps evaluate swallowing effort.
 - Verbal cueing keeps patient focused on swallowing. Positive reinforcement enhances patient's confidence in ability to swallow.
 - These are indications that suggest dysphagia and risk for aspiration.
 - Avoiding fatigue decreases the risk of aspiration.
 - Pockets of food in the mouth often indicate difficulty swallowing.
 - Reduces the risk of gastroesophageal reflux, which causes aspiration (Nowlin, 2006).
 - Mouth care after meals helps prevent dental caries and reduce colonization of bacteria to reduce the risk of pneumonia (Nowlin, 2006).
 - Reduces spread of microorganisms.
 - Determines if weight is stable and reflects adequate caloric level.

Unexpected Outcomes*Coughs, gags, food "stuck in throat," or left in mouth**Avoidance of certain textures of food
Weight loss***Related Interventions**

- Patient may require a swallowing evaluation.
- Initiate consultation with an SLP for swallowing exercises and techniques to improve swallowing and reduce risk of aspiration.
- Notify the nurse in charge, health care provider, and SLP of any symptoms that occurred during meal and which foods caused the symptoms.
- Change consistency and texture of food.
- Discuss findings with the nurse in charge, health care provider, SLP, or registered dietitian.

Recording and Reporting

- Document the following in the patient's chart: patient's tolerance of various food textures, amount of assistance required, position during meal, absence or presence of any symptoms of dysphagia, and amount eaten.
- Report any coughing, gagging, choking, or swallowing difficulties to the nurse in charge or the health care provider.

► BOX 42-6 NURSING DIAGNOSTIC PROCESS

Imbalanced Nutrition: More Than Body Requirements

Assessment Activities

Obtain height and weight

Data and Defining Characteristics

52-year-old man
Height: 180 cm
Weight: 122 kg
Body mass index (BMI) = 37.7

Obtain 24-hour food history

Lack of satiety
High fat and carbohydrate intake, three meals plus a large evening snack/day, three to four beers per day

Fluid

Fluid intake is cola, beer, and juice, all high caloric and lacking nutrient density

Physical assessment

Short of breath on walking
Large abdomen
Blood pressure: 158/88 mm Hg
Pulse: 102 beats/minute
Respirations: 32 breaths/minute

Laboratory values

Cholesterol and triglycerides elevated.
All others within normal limits.

Medication

None

Social

Eats out with family two or three times a week.

actual nutritional problem (e.g., inadequate intake) but may also involve problems that place the patient at risk for nutritional deficiencies, such as oral trauma.

The nursing diagnostic statement is based on defining characteristics present in the assessment database. The suspected health problem related to the nursing diagnosis is stated. The following are examples of nursing diagnoses of patients with nutritional problems:

- *Risk for aspiration*
- *Constipation*
- *Diarrhea*
- *Deficient fluid volumes*
- *Excess fluid volume*
- *Health maintenance, ineffective*
- *Health-seeking behaviours (nutrition)*
- *Knowledge deficit (nutrition)*
- *Ineffective management of therapeutic regimen, individuals*
- *Imbalanced nutrition: less than body requirements*
- *Imbalanced nutrition: more than body requirements*
- *Risk for imbalanced nutrition: more than body requirements*
- *Feeding self-care deficit*

❖ Planning

The planning for enhanced, optimal nutritional status requires a higher level of care than simply correcting problems. Information from multiple sources must be synthesized to devise an individualized approach to care that is relevant to the

Knowledge

- Role of dietitians and nutritionists in caring for patients with altered nutrition
- Impact of community support groups and resources in assisting patients to manage nutrition
- Impact of bad diets on patients' nutritional status

Experience

- Previous patient responses to nursing interventions for altered nutrition
- Personal experiences with dietary change strategies (what worked and what did not)

Planning

- Select nursing interventions to promote optimal nutrition
- Select nursing interventions consistent with therapeutic diets
- Consult with other health care providers (e.g., dietitians, nutritionists, physicians, pharmacists, physiotherapists, and occupational therapists) to adopt interventions that reflect the patient's needs
- Involve family when designing interventions

Standards

- Individualize therapy according to patient needs
- Select therapies consistent with established standards of normal nutrition
- Select therapies consistent with established standards for therapeutic diets

Qualities

- Display confidence when selecting interventions
- Creatively adapt interventions for the patient's physical limitations, culture, personal preferences, budget, and home care needs

Figure 42-6 Critical thinking model for nutrition planning.

patient's needs (Figure 42-6). Consider all data sources when developing a nursing care plan (Box 42-7). It is crucial to refer to published standards that are based on scientific findings.

In clinical situations, patients have multiple related problems. The concept map in Figure 42-7 shows the relationship of nursing diagnoses in a patient with myasthenia gravis.

Goals and Outcomes

Goals and outcomes and priorities of care reflect the patient's physiological, therapeutic, and individualized needs. Mutually planned goals negotiated between the patient, nurse, and dietitian help ensure success. An overall goal for an obese patient might be "to achieve appropriate BMI height-weight range or be within 10% of ideal body weight." To accomplish this, establish regular obtainable goals of moderate weight loss rather than one large overwhelming goal (Costain & Croker, 2005). These smaller goals or outcomes can help the patient achieve the goal:

- Daily nutritional intake meets the minimal DRIs
- Daily nutritional fat intake is less than 30%
- Sugared beverages are removed from diet
- Patient refrains from eating between meals and after dinner
- Patient loses 0.5 to 1 kg per week

► BOX 42-7 NURSING CARE PLAN

Imbalanced Nutrition: Less Than Body Requirements

Assessment

Belinda Wong, a nurse practitioner in a community health centre, is seeing 68-year-old Mrs. Cooper, who has a history of heart failure. Recently, Mrs. Cooper noticed a weight loss (15%). She has been taking an antidepressant (sertraline) for three months for an initial episode of depression related to the loss of her husband six months ago. Mrs. Cooper was referred for counselling three months ago for help with grief and depression. When Belinda inquired about Mrs. Cooper's financial situation, Mrs. Cooper responded that it was difficult living on an income from the Canada Pension Plan but she was able to manage.

Assessment Activities

Ask Mrs. Cooper about her food intake during the last two days.

Assess Mrs. Cooper's knowledge base by asking her what she sees as strengths of her diet, about areas in which her diet is ineffective, and what resources she uses in guiding her meal planning.

Assess her use of medication.

Ask Mrs. Cooper about social interaction.

Weigh Mrs. Cooper and assess her posture.

Observe Mrs. Cooper for signs of poor nutrition.

Palpate her muscles and extremities.

Data and Defining Characteristics

She says she drinks one glass of juice in the morning and two or three cups of coffee. She may eat a sandwich in the late afternoon. "I'm just not interested in food. It has no taste."

She says she does not need to worry about being overweight and believes her diet is adequate for her needs, as she does not feel hungry. She says she thinks she should be eating more vegetables and drinking more milk. Her meal preparation is "quick and easy," which pleases her. She says she is "too tired to fuss over food."

She takes the following prescribed medications as instructed on a daily basis: sertraline, digoxin (cardiac glycoside), chlorothiazide (diuretic), and captopril (antihypertensive).

Mrs. Cooper says she is lonely and does not get out much, although her psychologist recommended more socializing. Her friends at church call to ask her to come to meetings, but she is not ready. She says she tires easily.

This weight loss occurred over six months, down 11 kg. She has stooped posture. She has a low BMI of 17.

Dull, thinning hair
Dry, scaling skin
Pale conjunctivae and mucous membranes

2+ bilateral pitting ankle edema
Generalized poor muscle tone

Nursing Diagnosis: *Imbalanced nutrition: less than body requirements* related to a decreased ability to ingest food as a result of depression and loss of appetite associated with antidepressant use.

Planning

Goals (Nursing Outcomes Classification)*

Mrs. Cooper will progressively gain weight.

Mrs. Cooper will consume adequate nourishment each day.

Mrs. Cooper will exhibit no signs of malnutrition.

Expected Outcomes

Weight Control

Patient will gain 0.5 to 1 kg/month until goal of 59 kg is reached.

Nutritional Status: Nutrient Intake

Patient will ingest 1900 kcal/day, including 50 g of protein per day.

Physical assessment and laboratory values will be within normal limits.

*Outcome classification labels are adapted from Wilkinson, J. M., & Ahern, N. R. (2009). *Nursing diagnosis handbook* (9th ed.). Upper Saddle River, NJ: Pearson Prentice Hall.

Continued

► BOX 42-7 NURSING CARE PLAN—cont'd

Interventions (Nursing Interventions Classification)[†]

Nutritional Counselling

Coordinate a plan of care with Mrs. Cooper, her family doctor, therapist, and dietitian.

Rationale

Successful nutrition care planning involves an interdisciplinary approach (Brauer et al., 2006).

Individualize menu plans.

Encourages intake by incorporating food preferences (Paquet et al., 2003).

Teach Mrs. Cooper about the value associated with consulting *Eating Well with Canada's Food Guide*.

Health Canada (2007b) recommendations for food selections provide optimal nutrition.

Nutritional Monitoring

Monitor Mrs. Cooper monthly for weight gain, anemia, serum albumin level, and total lymphocyte count (TLC).

Weight gain should be slow and progressive. Serum albumin of 40 g/L and TLC of 1500/mm³ are within normal limits (Corbett, 2008).

Perform physical assessment of hair, eyes, mouth, skin, and muscle tone.

To monitor for improved nutritional status.

Nutritional Management

Encourage Mrs. Cooper to eat small meals and increase dietary intake to help offset anorexia secondary to use of sertraline.

Sertraline is a selective serotonin reuptake inhibitor (SSRI) medication; diminished taste and anorexia are common effects of SSRIs. Frequent small meals help to reduce anorexia-associated weight loss.

Encourage fluid intake early in the day.

Older adults need eight 250 mL glasses per day of fluid from beverage and food sources. Concentrating intake in the morning and early afternoon prevents nocturia (Meiner & Lueckenotte, 2006).

Encourage fibre intake.

Fibre helps prevent constipation.

Encourage Mrs. Cooper to have congregate meals (lunch at senior centre) five times per week.

Eating with others encourages good nutrition and promotes socialization with peers. Encouragement from health providers and from family and friends is helpful for women of ages 55 to 74 who do not exercise and eat nutritiously (Tannenbaum & Shatenstein, 2007).

[†]Intervention classification labels adapted from Bulechek, G. M., Butcher, H. K., & Dochterman, J. M. (Eds.). (2008). *Nursing interventions classification (NIC)* (5th ed.). St Louis, MO: Mosby.

Evaluation

Nursing Actions

Ask Mrs. Cooper to keep a food diary for three days.

Patient Response and Finding

Her diary reflects that she ate her main meal at the senior centre at noon, had fruit and grain products for breakfast, and had a sandwich with fruit and milk in the evening.

Achievement of Outcome

Mrs. Cooper is selecting more nutritionally rich foods, consistent with current guidelines.

Observe Mrs. Cooper's appearance.

Her skin is less pale, hair appears to be in better condition and styled. Ankle edema is present, but less than 1+.

Mrs. Cooper has improved physical parameters of nutrition; still needs follow-up.

Weigh Mrs. Cooper.

Weight gain of 2 kg in four weeks.

Weight gain is steady; she is still below ideal body weight.

Ask Mrs. Cooper about appetite and energy level.

Mrs. Cooper responds that on days when she eats at the senior centre, her appetite seems better and she "wants to do more things." She notes that weekends are very lonely.

Weekday support for nutritional status appears effective. Mrs. Cooper needs to increase activity status and nutritional intake during weekends.

Figure 42-7 Concept map for patient with myasthenia gravis.

The setting of goals and outcomes requires interdisciplinary input. A satisfactory care plan requires accurate exchange of information between disciplines.

Setting Priorities

By identifying patients at risk for nutritional problems, health providers can help prevent or minimize those problems through timely interventions. Although changes in the patient's weight are often gradual, improving nutritional intake is a priority. With acute illness or surgery, food intake is often altered. The priority of care may be to provide optimal preoperative nutrition support for patients with malnutrition. Resumption of food intake postoperatively depends on the return of bowel function, the extent of the surgical procedure, and presence of complications (see Chapter 48).

Sometimes other priorities take precedence. For example, patients who have had throat surgery must be out of pain and comfortable before nutritional priorities can be addressed. Note also that it is important to collaborate with the patient and family when setting care priorities. Food purchase and preparation may involve the family, and the care plan may not succeed without their commitment, involvement, and understanding.

Continuity of Care

In any health care setting, continuity of care is essential, including continuity of nutritional interventions. Hospital discharge planning should extend nutritional interventions to the home or long-term care facility. In extended settings, the dietitian monitors the patient's nutritional status and intake and makes recommendations for changes.

When patients require long-term care or care at home, occupational therapists can help them to choose assistive devices, such as large-handled utensils and cups with a space for the nose. Food preparation areas can be rearranged to maximize the patient's function. Speech language pathologists (SLPs) recommend appropriate dietary textures and feeding strategies and assist patients with swallowing exercises and techniques to reduce aspiration risk.

Implementation

Health Promotion/Illness Prevention

Nurses are in a key position to educate patients about proper nutritional habits that may prevent the development of many diseases. Early identification of potential or actual problems is the best way to avoid more serious problems. Outpatient and community-based settings are key locations for nursing assessment of nutritional practices and status. Patients with nutritional problems such as obesity may require help with menu planning and adherence strategies. Frequently, nurses are in a position to educate families about nutrition, inform them of community resources, and provide contact information so that families can direct questions to a dietitian or other professional nurse.

Insufficient income is the most significant barrier to healthy eating (Raine, 2005). Food selection and quantity are positively associated with income. To illustrate, the degree to which adequate amounts of thiamine and vitamins A and C are consumed correlates with level of income (Ricciuto & Tarasuk, 2006). Higher fruit and vegetable intake among children has been associated with better education of parents and with

parental knowledge of health, both of which relate to income status (Riediger et al., 2007). At the same time, lower socioeconomic status is associated with physical inactivity in Canadian adolescents (Janseen et al., 2006).

Approximately 3.7 million (15%) Canadians rely on food banks that are unable to supply recommended amounts of fresh fruits, vegetables, dairy products, and meats and alternatives (Irwin et al., 2007). The problem is worsened when children cannot access nutritional programs at schools (Henry et al., 2003). In Atlantic Canada, low-income lone mothers and their older children have poor diet quality (Glanville & McIntyre, 2006).

Although mandatory fortification of staple foods with micronutrients has helped to reduce income-related disparities (Ricciuto & Tarasuk, 2006), other interventions are also needed to counter the threat to good nutrition and health from lack of purchasing power at individual and collective levels. For those on limited budgets, food preparation can be modified for substances that need to be used sparingly; for example, bean or cheese dishes can often replace meat. Menu planning a week in advance helps patients comply with a specific diet, eat nutritiously, and stay within their budget. A nurse or dietitian may check menus for content. Often, simple tips can help, such as baking rather than frying to reduce fat intake, using lemon juice or spices to add flavour to low-sodium diets, and

avoiding grocery shopping when hungry because it can lead to spontaneous purchases of foods not included in meal plans. Strategies to help financially disadvantaged groups improve their nutrition include collective kitchens and gardens (Engler-Stringer & Berenbaum, 2005), coalitions with community-based organizations, antipoverty advocacy, and political commitment to policies of full employment (Power, 2005). Also important are public-awareness forums (Chapman, 2006) and a rights-based approach to food security at federal and provincial levels (Rideout et al., 2007) with support to families that have inadequate resources to meet their daily nutritional needs (Kurtz Landy, 2007). See Box 42-8 for an example of an innovative program that aims to increase food security for individuals, families, and communities.

safety alert Food safety is also an important public health issue. Food-borne illnesses can occur from poor hygiene practices and improper food storage or preparation. Nurses should educate patients about reducing the risks of food-borne illnesses (Table 42-7 and Box 42-9).

Acute Care

Many factors influence nutritional intake in acute care settings. Ill or debilitated patients often have loss of appetite (**anorexia**). The ketosis that accompanies starvation can further suppress

* BOX 42-8 FOCUS ON PRIMARY HEALTH CARE

Case Study

Foodshare (Toronto) is a nonprofit community organization that promotes “good healthy food for all” while reducing costs to the health care system. Since 1985, Foodshare has worked with communities to improve nonstigmatizing access to affordable, nutritious, sustainably produced food through innovative programs, food markets, and policy recommendations. Food security is facilitated through the creation and distribution of resources, training workshops, networks, and coalitions. Food issues are addressed from the growing and processing of food to its distribution, purchasing, cooking, and consumption. The Foodshare programs try to rebuild food skills that are quickly being lost in Canadian society as people abandon the family meal tradition and turn increasingly to fast foods and eating on the run. Foodshare partners (e.g., the Government of Ontario, Public Health Services, community clinics and shelters, school boards, and the Volunteer Action Online program), professionals, teachers, parents, and volunteers work together to promote a locally sourced, grow-your-own-food lifestyle in various ways:

- **FoodLink Hotline:** Telephone referral 416-392-6655 available Monday to Friday 10 A.M. to 4 P.M. for those seeking information on food programs.
- **Community gardening programs:** Information, training (e.g., composting workshops), and resources provided to individuals and groups in preparing gardens and harvesting the produce.
- **Incubator Kitchen:** A fully equipped kitchen that provides groups without access to a commercial kitchen the opportunity to come together to plan and prepare low-cost nutritious meals in bulk.
- **The Good Food Box:** This food distribution system provides fresh fruit and vegetables at wholesale prices to over 200 community drop-off sites across the City of Toronto reaching 12,000 people. Individuals and families who are part of neighbourhood-based groups pay for and order food in advance. The program workers purchase foods in bulk to support local farmers; volunteers and

staff pack and deliver the food boxes to the drop-off sites. All boxes are accompanied by a newsletter offering nutrition information and economical food preparation tips. The “Reach for 5” basket, geared to seniors, contains prepared, cut-up fruit and vegetables.

- **Power Soups and Power Meals:** Foodshare makes dense soups, meals, and nutrition/training workshops available at a heavily subsidized price to Toronto shelters and drop-ins serving the homeless, which enables the underprivileged to have access to a wholesome meal.
- **Baby Nutrition:** Food-related activities for families with infants and preschoolers include workshops on making homemade baby food from fresh affordable food and cooking with kids.
- **Partners for Student Nutrition:** Foodshare works with Toronto Public Health and other community agencies to sponsor 300 student nutrition programs in Toronto.
- **Focus on Food:** A training program for marginalized youth focusing on community service and developing cooking, gardening, and nutrition skills.
- **Field to Table Wholesale Produce:** A community development project that makes fresh fruit and vegetables available and affordable to schools (e.g., the “Salad Bar” project) in order to promote increased consumption of fresh, nutritious foods among children.
- **Partnership with Canadian Mental Health Association:** Individuals living with mental health challenges earn minimum wage and gain valuable job skills producing sprouts and seedlings for sale.
- **Online food security resource centre:** An interactive library of electronic and print newsletters, food program manuals, community resource sites such as sustainable agriculture and anti-poverty issues with links to key Web sites, listservs, e-bulletins, and archived, current, and upcoming workshops.

► TABLE 42-7 Food Safety

Food-Borne Disease	Organism	Food Source	Symptoms*
Botulism	<i>Clostridium botulinum</i>	Improperly home-canned foods, smoked and salted fish, ham, sausage, shellfish	Symptoms vary from mild discomfort to death in 24 hours, initial nausea and dizziness progressing to motor (respiratory) paralysis
Escherichia coli	<i>Escherichia coli</i> 0157:H7	Undercooked meat (ground beef)	Severe cramps, nausea, vomiting, diarrhea (may be bloody), renal failure. Appears 1–8 days after eating, lasts 1–7 days
Listeriosis	<i>Listeria</i> species <i>L. monocytogenes</i>	Soft cheese, meat (hot dogs, pâté, lunch meats), unpasteurized milk, poultry, seafood	Severe diarrhea, fever, headache, pneumonia, meningitis, endocarditis, appears 3–21 days after infection
Perfringens enteritis	<i>Clostridium</i> species <i>C. perfringens</i>	Cooked meats, meat dishes held at room or warm temperature	Mild diarrhea, vomiting. Appears 8–24 hours after eating, lasts 1–2 days
Salmonellosis	<i>Salmonella</i> species <i>S. typhi</i> <i>S. paratyphi</i>	Milk, custards, egg dishes, salad dressing, sandwich fillings, polluted shellfish	Mild to severe diarrhea, cramps, vomiting. Appears 12–24 hours after ingestion, lasts 1–7 days
Shigellosis	<i>Shigella</i> species <i>S. dysenteriae</i>	Milk, milk products, seafood, salads	Mild diarrhea to fatal dysentery. Appears 7–36 hours after ingestion
Staphylococcus	<i>Staphylococcus</i> species <i>S. aureus</i>	Custards, cream fillings, processed meats, ham, cheese, ice cream, potato salad, sauces, casseroles	Severe abdominal cramps, pain, vomiting, diarrhea, perspiration, headache, fever, prostration. Appears 1–6 hours after ingestion, lasts 1–2 days

*Symptoms are generally more severe for youngest and oldest age groups.

* BOX 42-9 PATIENT TEACHING

Food Safety

Objectives

- Patient will verbalize measures to prevent food-borne illness.
- Patient will understand the primary types of illness and how they are transmitted.
- Patient will not experience food-borne illness.

Teaching Strategies

Populations particularly at risk are older and younger people and immunosuppressed individuals. Instruct patients on the following:

- Wash hands with warm, soapy water before touching or eating food.
- Cook meat, poultry, fish, and eggs until they are well done.
- Wash fresh fruits and vegetables thoroughly.
- Do not eat raw meats or drink unpasteurized milk.
- Do not buy or consume food that has passed the expiration date.
- Keep foods properly refrigerated at 4°C and frozen at -18°C.
- Wash dishes and cutting boards with hot, soapy water or use a bleach sanitizer using 5 mL bleach in 750 mL water.
- Refrigerate leftovers within two hours. Do not save for more than four days in the refrigerator.
- Wash dishcloths, towels, and sponges regularly, or use paper towels.
- Clean the inside of the refrigerator and microwave regularly to prevent microbial growth.

Evaluation

- Ask patient to describe measures to prevent food-borne illnesses.
- Observe the patient at home for safe practices, if making a home visit.

Source: Government of Canada. (2010). *Safe food handling and preparation*. Retrieved from <http://www.foodsafety.gc.ca/english/fssa/prepare.asp>.

appetite, as can the pain that results from surgical procedures and trauma. Mealtimes, during hospitalizations, are often interrupted or the patient is too fatigued or uncomfortable to eat. Worry about families, finances, employment, or illness often interferes with getting an adequate diet. Medications may impair taste, cause nausea, interfere with absorption, or affect metabolism. Diagnostic testing may disrupt mealtimes or require a nothing by mouth (NPO) status. Patients who are NPO and receive only standard IV fluids for more than seven days are at nutritional risk.

Nurses must continuously assess patient nutritional status and plan interventions that promote normal dietary intake, digestion, and metabolism of nutrients. Patients may have a gradual progression of dietary intake or need therapeutic diets to manage their illnesses (Box 42-10).

Promoting Appetite. In providing an environment that promotes a patient's appetite, it is important to eliminate unpleasant odors, provide oral hygiene as needed to remove disagreeable tastes, and maintain patient comfort. Certain medications can affect dietary and nutrient intake; for example, insulin, glucocorticoids, and thyroid hormones affect metabolism. Other medications, such as antifungal agents, can affect taste. Some psychotropic medications affect appetite, cause nausea, and alter taste. At times the nurse and dietitian can help the patient select foods to reduce the altered taste sensations or nausea. In other situations, medication may need to be changed. Physicians may order pharmacological agents to stimulate appetite (e.g., cyproheptadine [Periactin], megesterol [Megace]) or to manage symptoms that interfere with nutrition.

Assisting Patients With Feeding

Many conditions, including cancer, stroke, and neuromuscular disorders, can cause feeding difficulties. The task of feeding requires nursing knowledge and skilled intervention to protect patient safety, independence, and dignity.

► BOX 42-10

Diet Progression and Therapeutic Diets**Clear Liquid**

This diet is limited to broth, bouillon, coffee, tea, carbonated beverages, clear fruit juices, gelatin, or Popsicles.

Thickened Liquid

All liquids (e.g., juice, tea, coffee, water, etc.) must be thickened to the appropriate consistency (nectar, honey, or pudding) as recommended by the SLP/feeding team when thin fluids cannot be safely swallowed and may be aspirated.

Full Liquid

To a clear- or thickened-liquid diet can be added smooth-textured dairy products, custards, refined cooked cereals, vegetable juice, puréed vegetables, or any fruit juices.

Puréed

This diet includes all of the above with the addition of scrambled eggs, puréed meats, vegetables, fruits, or mashed potatoes and gravy.

Mechanical Soft

This diet includes all of the above with the addition of ground or finely diced meats, flaked fish, cottage cheese, cheese, rice, potatoes, pancakes, light breads, cooked vegetables, cooked or canned fruits, bananas, soups, or peanut butter.

Soft or Low Residue

Low-fibre, easily digested foods, such as pastas, casseroles, moist tender meats, canned cooked fruits and vegetables, desserts, cakes, and cookies without nuts or coconut, can be added.

High Fibre

This diet includes fresh uncooked fruits, steamed vegetables, bran, oatmeal, and dried fruits.

Low Sodium

A low-sodium diet is limited to 4 g (no added salt), 2 g, 1 g, or 500 mg sodium (severe sodium restriction), requiring selective food purchases.

Low Cholesterol

This diet is restricted to <200 mg/day cholesterol, in keeping with the National Cholesterol Education Program (NCEP) recommendations (Grundy et al., 2004).

Diabetic

In general, people with diabetes should follow a healthy diet recommended for the general population in *Eating Well With Canada's Food Guide* (CDA, 2008; Health Canada, 2007b). This includes consuming a variety of foods from the four food groups (grain products, vegetables and fruits, milk products, meat and alternatives), attaining and maintaining a healthy body weight, decreasing total fat intake to <30% of calories, and ensuring an adequate intake of carbohydrate, protein, essential fatty acids, vitamins, and minerals.

Regular

Dietary restrictions are not necessary unless specified.

Before Feeding. Assess the patient's risk of aspiration (see "Assessment" in this chapter and Skill 42-1). The patient should sit as upright as possible with head tilted slightly forward and may be supported by pillows, foam wedges, or rolled towels. Do not feed a patient who is lying back or has the neck arched or hyperextended because these positions

create an open airway susceptible to aspiration. Glasses, hearing aids, and dentures should be functioning and in place. Clothing and bedding should be protected with napkins, towels, or aprons, and these items should not be called "bibs." Ensure that suction apparatus at the bedside has been checked.

During Feeding. Keep the patient upright. Use a rocking motion of utensil on the patient's tongue. When the patient has hemiplegia (one-sided weakness), the head should be tilted slightly toward the stronger side to avoid pouching (Nursing Times, 2003). Place small bites of food on the stronger side of the patient's mouth. If indicated by the feeding/swallowing team, allow the patient to take a drink between each mouthful of food to ease the process of eating. The patient should be observed for pouching of food. A metal teaspoon is usually the best utensil to use for feeding patients with bite reflexes.

Assess swallowing during feeding and give patients with dysphagia enough time to chew. Allow at least 5 to 10 seconds or longer for each bite or sip. Observe for two completed swallows between mouthfuls. The patient's Adam's apple should move up and down. If the food is still present, offer an empty spoonful to stimulate swallowing.

The nurse who is helping the patient to eat should sit in the patient's line of vision and provide prompting, encouragement, and direction, both verbally and nonverbally, when appropriate. The nurse avoids hovering with the next spoonful of food as this may cause a patient to hurry and worsen any swallowing difficulties. Patience, attention, and time are essential. When possible, try to heed special requests, such as for the food to be warmed up. Promote comfort and a sense of independence by providing opportunities for patients to direct the order and speed at which they want to eat. Give the patient as much choice as possible; for instance, ask if the patient wants peas and potatoes together or separate on the spoon. The family can be asked about the patient's favourite foods. Because mealtime is usually a social activity, it is important that nurses and other health providers talk to patients during meals. Use this opportunity to educate patients about therapeutic diets, medications, or adaptive devices.

Patients with visual deficits also need special assistance. Position food within the patient's visual field. If the patient wears glasses or contact lenses, they should be clean and in place. Patients with poor vision may be able to feed themselves if adequate care and information is given. Identify the location of the food on the plate as if it were a clock (e.g., meat at 9 o'clock and vegetable at 3 o'clock). Tell the patient where the beverage is located in relation to the plate. Patients with decreased motor skills may retain more independence by using large-handled adaptive utensils, which are easier to grip and manipulate.

When food intake is less than usual because of illness or fatigue, nutrient-dense items should be provided first. Small frequent meals, five to six per day, may be required.

After Feeding. The patient should remain upright for 30 minutes after eating. Check again for pocketing of food. If the patient needs to lie down because of fatigue, raise the head of the bed to sitting-up level. Note and document intake. Identify if any particular food was eaten faster (e.g., a preference) or with difficulty (e.g., soft meat may need to be replaced with ground). Report and document any instances of choking and fatigue. After each meal, the patient should perform oral hygiene.

Restorative and Continuing Care

Patients discharged from a hospital with dietary prescriptions often need dietary education to plan meals that meet specific therapeutic requirements. Restorative care includes immediate postsurgical care and routine medical care and is pertinent to hospitalized and home care patients.

❖Evaluation

Care plans should reflect achievable goals and outcomes. You will need to evaluate outcomes of nursing actions and be alert for signs that goals are being met. Allow adequate time for testing each nursing approach to a problem.

Patient Care

The effectiveness of nutritional interventions is best measured by meeting the expected patient outcomes and goals of care (Figure 42-8). Nutrition therapy does not always produce rapid results. Ongoing comparisons may be made with baseline measures of weight, serum albumin or prealbumin, and protein and kilocalorie intake. Medications may produce unwanted side effects. If gradual weight gain is not observed, or if weight loss continues, the prescription may need to be

Figure 42-8 Critical thinking model for nutritional evaluation.

adjusted. Changes in health condition may indicate a need to change the nutritional care plan. Interdisciplinary members of the health team should be consulted, and the patient should be an active participant whenever possible. The patient's ability to incorporate dietary lifestyle changes with the least amount of stress or disruption will ensure success. When expected outcomes are not met, revise the interventions or outcomes on the basis of the patients' needs and preferences.

Patient Expectations

Patients expect competent and accurate care. They expect nurses to alter the care plan if outcomes of nutritional therapies are unsuccessful. Your expectations and health values may differ from those held by patients. By working closely with patients, you can get to know their expectations and try to meet them within the limits of their conditions and treatments.

Self-Monitoring of Blood Glucose

Self-monitoring of blood glucose (SMBG) is a cornerstone of diabetes management. By providing a real-time blood glucose reading, SMBG enables the patient to make self-management decisions regarding diet, exercise, and medication.

Portable blood glucose meters are used at the hospital bedside and by patients who perform SMBG independently. In Canada, the only continuous glucose monitoring system (CGMS) available is the Medtronic MiniMed Paradigm REAL-Time System. A sensor is inserted under the skin, and data are sent from the sensor to a transmitter, which displays the glucose value on an insulin pump continuously; values are updated every five minutes. This system assists the patient and health care provider to identify trends and track patterns; thus, it is particularly useful for managing insulin therapy, alerting the patient during episodes of hypoglycemia and hyperglycemia, and allowing prompt, immediate, and corrective action.

The blood glucose (BG) level reported by a laboratory is sometimes higher than the measurement by the patient's home glucose monitor or the hospital's portable meter. This is because some meters measure capillary blood glucose from whole blood (via finger stick), whereas laboratory venous samples yield plasma readings. Plasma samples, or venous samples, are <20% higher when the BG levels are >4.2mmol/L. Less variation is recommended when BG levels are less than or equal to 4.2mmol/L (CDA, 2008). Most meters are automatically calibrated to give a "plasma" test reading (although whole blood was used for the sample) so that home readings can be more readily compared with laboratory values.

Instructions for using a blood glucose meter (BGM) accompany each product. Because errors in monitoring technique can cause errors in management strategies, thorough patient education is crucial. Once initial education has occurred, follow-up educational sessions should take place at each subsequent patient contact and also be timed to coincide with regular appointments for reassessment. In addition, patients must be taught to calibrate their BGM and use control solutions. In Canada, the control solutions are not included in the BGM kits and are not stocked by most pharmacies. A person with diabetes must call the company to ask for the control solution, and it will be sent to them at no charge. The control solution has a very narrow expiry date and once opened lasts only three months. The person must run the control test every week.

The chief advantage of SMBG is that it supplies immediate information about blood glucose levels that can be used to make adjustments in food intake, activity patterns, and medication dosages. It also produces accurate records of daily glucose fluctuations and trends, as well as alerting the patient to acute episodes of hyperglycemia and hypoglycemia. Furthermore, it provides patients with a tool for achieving and maintaining specific glycemic goals. SMBG is recommended as an essential part of daily diabetes management for all people using insulin or oral hypoglycemic agents (OHAs). The frequency of monitoring depends on several factors, including the patient's glycemic goals, the type of diabetes that the patient has, the patient's ability and willingness to perform the test independently, and the treatment regimen. It is recommended that patients with type 1 diabetes test at least three times per day and include both preprandial and postprandial testing. Those using an insulin pump may test more frequently. People with type 2 diabetes treated with OHAs or through lifestyle changes alone have more variable and individualized testing regimens. For patients with type 2 diabetes treated with once-daily insulin and OHAs, monitoring at least once daily is recommended (CDA, 2008).

Blood glucose testing should also be performed whenever hypoglycemia is suspected so that immediate action can be taken if necessary. When the person with diabetes is ill, the blood glucose should be tested every two to four hours to determine the effects of this stressor on blood glucose level (CDA, 2008). (See Skill 42-2 for a description of how to monitor blood glucose.)

SMBG empowers the patient to be an active partner in the treatment of diabetes. Achieving the desired level of patient participation requires time and effort from the health

care provider. If a patient is visually or cognitively impaired or has limited manual dexterity, the degree to which SMBG can be performed independently must be evaluated carefully. Nurses working in home health and outpatient settings may need to identify caregivers who can assume this responsibility.

Enteral Tube Feeding

Enteral nutrition refers to nutrients given via the gastrointestinal tract. When the patient cannot ingest food but is still able to digest and absorb nutrients, enteral tube feeding is indicated. Feeding tubes can be inserted through the nose (or orally if necessary) into the stomach or intestines (nasogastric-oro gastric or nasointestinal-oro intestinal tubes), surgically through a stoma (a surgically created opening) into the stomach or jejunum (gastrostomy or jejunostomy tubes), or endoscopically (percutaneous endoscopic gastrostomy [PEG] or jejunostomy [PEJ] tubes). A registered nurse may insert nasogastric or orogastric tubes for abdominal decompression and for enteral feedings with an order from a physician (Best, 2007; Dugas & Knor, 1995). Large-bore sump tubing nasogastric tubes are most often used for both decompression and short-term enteral feeding, whereas small-bore, silastic tubing with insertion stylet is used for longer-term feeding needs (Bankhead et al., 2009). All other tubes must be inserted by a physician. In some settings (e.g., the ICU), a large tube is used to start the tube feed and if the patient tolerates it for the first 24 to 48 hours, a small-bore tube is then inserted. As well, if the patient has a small-bore tube placed in the duodenum, the physician may elect to leave the sump tube in the stomach for

Text continued on p. 1087

► SKILL 42-2 Blood Glucose Monitoring

When you cannot perform venipuncture to obtain capillary blood, skin puncture is an alternative method to reduce the frequency of needle sticks and for self-management of diabetes mellitus. The procedure is less painful than venipuncture, and patients can perform this procedure. The development of blood glucose testing strips, home glucose monitors, and the skin puncture method have revolutionized home management care for patients with diabetes mellitus.

There are two methods for self-testing of blood glucose level. Both methods require obtaining a large drop of blood by skin puncture. You can use a hand-held single-use lancet or an automatic lancet-holder device. You then apply the drop of blood on the specially prepared testing strip.

The first self-testing method involves visually reading the reagent strip by comparing it with the colour chart on the container. Examples of such strips are Chemstrip bG, Glucostix, and TrendStrips. If the colour on the strip appears between two reference blocks on the chart, you may need to estimate the results. Consequently, results of blood glucose measurement using this method may not always be accurate.

The second type of blood glucose monitoring entails the use of reflectance meters (Figure 42-9). A variety of meters are on the market, such as the Glucometer II (Ames), Accu-Chek III (Boehringer Mannheim), Glucoscan 3000 (LifeScan), and OneTouch (LifeScan). After a drop of blood from the skin puncture is placed on the testing strip, the meter provides an accurate measurement of blood glucose level in less than 60 seconds.

For these meters, a wet-wash or dry-wipe method of testing is used. To perform a wet wash, the user flushes the blood-coated

testing strip with water before inserting the strip into the glucose meter. The dry-wipe method requires the user to wipe off the blood-coated testing strip with a dry cotton ball before making a reading. Some products do not require blood to be flushed or wiped before a reading. The various methods allow measurement of blood glucose between 1.1 and 44.4 mmol/L, which is a sensitive measurement of blood glucose level.

These meters differ in several ways: the amount of blood needed for each test, testing speed, overall size, ability to store test results in memory, cost of the meter, and cost of test strips (Klonoff, 2010). Some larger meters are voice activated, which is helpful for older adult patients with visual impairments. Glucose readings may be from 0 to 44.4 mmol/L. The amount of time to complete the glucose testing with the current glucose meters varies from 5 seconds to 50 seconds. Some meters can be programmed to monitor glucose levels for a continuous 72 hours.

Most meters allow for alternative sites, such as the forearm, palm, and thigh. Two new methods of obtaining glucose measurement are available on the market. Minimally invasive glucose meters have a very small fine plastic sensor inserted through the abdomen, and they provide continuous readings of blood glucose levels. A bio-sensor is taped on the external abdomen (Figure 42-10). Using a hand-held wireless meter, the patient activates the biosensor to transmit the blood glucose level at any time without puncturing the skin. Another model, the noninvasive glucose meter, punctures the skin not with a needle but with laser technology.

SKILL 42-2 Blood Glucose Monitoring—cont'd

Figure 42-10 A tiny sensor (A) implanted under skin transmits continuous reading to receiver (B), to alert wearer of any deviation from desired glucose target range. Readings are displayed and stored on the monitor (C). **Source:** Courtesy of DexCom, Inc.

Delegation Considerations

The task of measuring blood glucose level after skin puncture (capillary puncture) can be delegated to an unregulated care provider (UCP) who is specifically instructed in performing the skill. The nurse must first assess the patient to determine that it is appropriate to delegate blood glucose monitoring. If the patient's condition changes frequently, this task should not be delegated. The nurse directs the UCP by

- Explaining appropriate sites to use for puncture and when to obtain glucose levels
- Reviewing expected levels and when to report to the nurse unexpected glucose levels

Equipment

- Antiseptic swab
- Cotton ball or tissue
- Sterile lancet or blood-letting device
- Heel-warming device (*optional*)
- Paper towel
- Blood glucose meter (e.g., OneTouch)
- Blood glucose test strips (brand determined by meter used)
- Disposable gloves

Procedure

STEPS

1. Assess understanding of procedure and purpose. Determine whether patient with diabetes mellitus understands how to perform test and realizes importance of glucose monitoring.
2. Determine whether specific conditions need to be met before or after sample collection (e.g., with fasting, after meals, after certain medications, before insulin doses).
3. Determine whether risks exist for performing skin puncture (e.g., low platelet count, anticoagulant therapy, bleeding disorders).

RATIONALE

- Data set guidelines for nurse to develop teaching plan.
- Dietary intake of carbohydrates and ingestion of concentrated glucose preparations alter blood glucose levels.
- Abnormal clotting mechanisms increase risk for local ecchymosis and bleeding.

Continued

► SKILL 42-2 Blood Glucose Monitoring—cont'd

4. Assess area of skin that you will use as puncture site. Inspect the patient's fingers, toes, and heel. Alternative sites are the palm, arm, and thigh. Avoid areas that have bruises and open lesions.
 5. Review health care provider's order for times and frequency of measurement.
 6. If diabetic patient performs test at home, assess patient's ability to handle skin-puncturing device. If patient chooses, he or she may wish to continue self-testing while in hospital.
 7. Expected outcomes after completion of procedure:
 - Puncture site shows no evidence of bleeding or tissue damage.
 - Blood glucose level is normal.
 - Patient demonstrates procedure.
 - Patient explains test results.
 8. Explain procedure and purpose to patient or family, or both. Offer patient and family opportunity to practise testing procedures. Provide resources and teaching aids for patient.
 9. Perform hand hygiene before procedures.
 10. Instruct patient to perform hand hygiene with soap and warm water, if patient is able.
 11. Position patient comfortably in chair or in semi-Fowler's position in bed.
 12. Remove test strip from container, then tightly seal cap. Check the code on the test strip vial.
 13. Turn on glucose meter, if necessary.
- Sides of fingers, toes, and heels are commonly selected because they have fewer nerve endings.
 - Measurements at alternative sites are meter specific and may be different from measurements at traditional sites (Corbett, 2008). The puncture site should not be edematous, inflamed, or recently punctured because these factors cause increased interstitial fluid and blood to mix and also increase the risk for infection.
 - Health care provider determines test schedule on basis of patient's physiological status and risk for glucose imbalance.
 - Patient's physical health may change (e.g., vision disturbance, fatigue, pain, disease process), preventing patient from performing test.
 - Hemostasis achieved. Lancet or needle did not puncture skin too deeply.
 - Normal fasting glucose level is 4 to 6 mmol/L, indicating good metabolic control.
 - Patient demonstrates psychomotor learning.
 - Patient validates knowledge.
 - Such explanations promote understanding and cooperation.
 - Hand hygiene reduces transfer of microorganisms.
 - Instructions promote skin cleansing and vasodilation at selected puncture site. Hand washing establishes practice for patient when test is performed at home. Because of its ability to remove food residue from the hands and fingers, hand washing is superior to the use of alcohol pads to cleanse the test site.
 - This position ensures easy accessibility to puncture site. Patient will assume position when self-testing.
 - Sealing cap protects unused strips from accidental discolouration caused by exposure to air or light. Code on test strip vial must match code entered into the glucose meter.
 - Turning on activates meter.

Critical Decision Point: Some monitors are activated when the test strip is inserted and therefore do not have a specific on-off switch.

14. Insert strip into glucose meter (refer to manufacturer's directions), and make necessary adjustments (see Step 14 illustration).
- Some machines must be calibrated; others require zeroing of timer. Each meter is adjusted differently.

Step 14 Load test strip into meter. **Source:** Courtesy of Accu-Chek Glucometer.

15. Remove unused glucose test strip from meter and place on paper towel or clean, dry surface with test pad facing up (see manufacturer's directions).
 16. Apply disposable gloves.
 17. Choose puncture site. Puncture site should be vascular. In adults, select lateral side of finger; be sure to avoid central tip of finger, which has more dense nerve supply.
- Moisture on strip can alter accuracy of final test results.
 - Wearing gloves reduces risk for contamination by blood.
 - Vascularity ensures free flow of blood after puncture.

► SKILL 42-2 Blood Glucose Monitoring—cont'd

18. Hold the finger that you will puncture in dependent position while gently massaging finger toward puncture site.
 19. Clean site with antiseptic swab, and allow it to dry completely.
 20. Remove cover of lancet or blood-letting device. Hold lancet perpendicular to puncture site, and pierce finger or heel quickly in one continuous motion (do not force lancet).
 21. Some employers use lancet devices with an automatic blade retraction system. This reduces the possibility of self-sticks, preventing exposure to blood-borne pathogens. Place blood-letting device firmly against side of finger and push release button, causing needle to pierce skin (see Step 21 illustration).
 22. Wipe away first droplet of blood with cotton ball. (See manufacturer's directions for meter used.)
 23. Lightly squeeze puncture site (without touching) until a second large droplet of blood has formed (see Step 23 illustration). Repuncturing is necessary if large enough drop does not form to ensure accurate test results. (See manufacturer's direction regarding how blood is applied.)
- Massage increases blood flow to area before puncture.
 - The site must be allowed to dry because alcohol can cause blood to hemolyze.
 - Cover keeps tip of lancet or needle sterile.
 - Blood-letting devices are designed to pierce skin to specific depth, ensuring adequate blood flow. Perpendicular position ensures proper skin penetration.
 - First drop of blood may contain more serous fluid than blood cells.
 - Adequate-sized droplet is needed to activate monitor and obtain accurate results. Excessive squeezing of tissues during blood sample collection may contribute to pain, bruising, scarring, and hematoma formation (Pagana & Pagana, 2007).

Step 21 Prick side of patient's finger with lancet. **Source:** Courtesy of Accu-Chek Glucometer.

Step 23 Squeeze puncture site until a large droplet of blood is expressed.

Critical Decision Point: Diabetic patients frequently have peripheral vascular disease. This makes it difficult to produce a large drop of blood after a fingerstick. To improve blood flow, be sure to hold patient's finger in dependent position before puncturing.

24. Obtain test results.
- Exposure of blood to test strip for prescribed time ensures proper results.

Critical Decision Point: Some meters (such as OneTouch [LifeScan]) require blood sample to be applied to test strip already in the meter. Once the drop of blood is applied, the meter automatically calculates the reading.

- A. Be sure meter is still on. Bring test strip in the meter (in this example, an Accu-Check) to the drop of blood (see Step 24A illustration). The blood will be absorbed into the test strip (see manufacturer's instructions).
- Blood is absorbed into strip, and glucose device will show message on screen to signal that enough blood is obtained.

Critical Decision Point: Do not scrape blood onto the test strips or apply blood to wrong side of test strip. This prevents accurate glucose measurement. Ensure enough blood is applied to completely fill the test window. Otherwise a false reading or error message will be displayed.

Continued

► SKILL 42-2 Blood Glucose Monitoring—cont'd

- B. The blood glucose test result will appear on the screen (see Step 24B illustration). Some devices beep when measurement is completed.

Step 24A Touch the test strip to the blood drop. Blood is absorbed into the test strip. **Source:** Courtesy of Accu-Chek Glucometer.

25. Turn meter off. Dispose of test strip, lancet, and gloves in proper receptacle.
26. Discuss test results with patient.
27. Reinspect puncture site for bleeding or tissue injury.
28. Compare glucose meter reading with normal blood glucose levels and previous test results.
29. Ask patient to discuss procedure.
30. Ask patient to explain test and results.

Unexpected Outcomes

Puncture site bruised and continues to bleed

Blood glucose level above or below target range

Glucose meter malfunction

Patient misunderstanding of procedure and results

Step 24B Results appear on meter screen. **Source:** Courtesy of Accu-Chek Glucometer.

- Meter is battery powered. Proper disposal reduces risk for needlestick injury and spread of infection.
- Discussion promotes participation and provides a perfect teaching opportunity for continued SMBG testing.
- Site is possibly a source of discomfort and infection.
- Comparison helps determine whether glucose level is normal.
- Discussion validates patient's level of learning.
- Results of test may cause anxiety. Patient may misunderstand specific step of procedure.

Related Interventions

- Apply pressure.
- Elevate hand above level of heart
- Notify health care provider.
- Continue to monitor patient.
- Check for medication orders regarding deviations in glucose level.
- Administer insulin or carbohydrate source as ordered, depending on glucose level.
- Notify health care provider.
- Review instructions for troubleshooting glucose meter.
- Repeat test.
- Call the 1-800 company phone number found at the back of every BG testing meter.
- Repeat instructions to patient.
- Have patient demonstrate procedure.

► SKILL 42-2 Blood Glucose Monitoring—cont'd

Recording and Reporting

- In nurses' notes or special flow sheet, record procedure, glucose level, and action taken for abnormal range.
- Describe response, including appearance of puncture site, in nurses' notes.
- Record and report abnormal blood glucose levels.
- Stress importance of timing the testing of blood glucose levels, particularly in patients with diabetes mellitus.

Teaching Considerations

- Provide information on where a patient with diabetes mellitus can obtain testing samples, if applicable. When possible, teach with the same meter that the patient will use at home.
- Provide patient with information on where to obtain assistance if glucose meter has malfunctioned.
- Instruct patient in what to do and whom to contact if glucose meter malfunctions.

Pediatric Considerations

- Young children should be allowed to choose puncture site.
- Heel and great toe are common puncture sites in infants.
- It is necessary to assess for localized complications in heels of premature infants who must have blood drawn repeatedly.
- Heel warming facilitates obtaining a specimen from a neonate.
- Infection or abscess of the heel and necrotizing osteochondritis are the most serious complications of heelstick puncture in infants.
- To avoid osteochondritis, the puncture should not be deeper than 2.4 mm and is made at the outer aspect of the heel (Hockenberry & Wilson, 2007).
- The earlobe should be used to obtain blood in older pediatric patients (Pagana & Pagana, 2007).
- Young children should be allowed with parent to demonstrate technique; technique can be incorporated in play activity for further understanding.

Age-Related Considerations

- Warming fingertips may facilitate obtaining specimen.
- Some older adults have vision or dexterity problems that interfere with performing self-fingersticks.

Home Care Considerations

- Patients can use glucose meters routinely in their homes.
- Patients should be encouraged to attend a diabetic support group if it is needed.
- As visual acuity may affect a patient's ability to perform self-testing at home (Corbett, 2008), there are new BG testing meters that have talking ability.

Reproduced from Perry, A. G., & Potter, P. A. (2010). *Clinical nursing skills and techniques* (7th ed., pp. 1153–1158). St Louis, MO: Elsevier/Mosby.

gastric decompression and prevent vomiting or aspiration. If enteral nutrition therapy is to be administered for less than four weeks, nasoenteral tubes may be used. Surgical or endoscopically placed tubes are preferred for long-term feeding (>4 weeks) to reduce the discomfort of a nasal tube and to provide a more secure, reliable access (Pearce & Duncan, 2002). Patients with gastroparesis (decreased or absent innervation to the stomach causing delayed gastric emptying) or esophageal reflux, those at risk for aspiration, and those with a history of aspiration pneumonia require placement of tubes beyond the stomach into the intestine (Metheny, 2006).

Box 42-11 lists indications for enteral nutrition. The nurse inserts the nasoenteral tube (Skill 42-3), and the nurse or others, including family in the home setting, can administer enteral tube feedings. It is highly recommended that tube placement be verified by X-ray examination before the patient receives the first enteral feeding.

Enteral nutrition has been used successfully after surgery or trauma to provide fluids, electrolytes, and nutritional support. Gastric ileus may prevent nasogastric feedings, while nasointestinal or jejunostomy tubes allow successful postpyloric feeding of formula directly into the small intestine or jejunum or beyond the pyloric sphincter of the stomach

(Ellett, 2006). Enteral feedings can be administered through a nasoenteric tube (Skill 42-4) or via a gastrostomy or jejunostomy tube (Skill 42-5).

Initiating Enteral Tube Feedings

Enteral formulas are usually one of four types. **Polymeric formulas** (1.0 to 2.0 kcal/mL) include milk-based blenderized foods prepared by hospital dietary staff or in the patient's home. The polymeric classification also includes commercially prepared whole nutrient formulas. For this type of formula to be effective, the patient's gastrointestinal tract must be able to absorb whole nutrients. **Modular formulas** (3.8 to 4.0 kcal/mL) are single-macronutrient (e.g., protein, glucose, polymers, or lipids) preparations and are not nutritionally complete. This type of formula is added to other foods for meeting the patient's individual nutritional needs. **Elemental formulas** (1.0 to 3.0 kcal/mL) contain predigested nutrients that are easier for a partially dysfunctional gastrointestinal tract to absorb. Finally, **specialty formulas** (1.0 to 2.0 kcal/mL) are designed to meet specific nutritional needs in certain illnesses (e.g., liver failure, pulmonary disease, or human immunodeficiency virus [HIV] infection).

Text continued on p. 1099

► BOX 42-11 Indications for Enteral Nutrition

Cancer

- Head and neck
- Upper gastrointestinal tract

Critical Illness or Trauma

- Respiratory failure with prolonged intubation/inadequate oral intake
- Patients in critical care with suspected/evidence of catabolism
- Trauma patients, especially those in a hypermetabolic state (e.g., burns)

Neurological and Muscular Disorders

- Brain neoplasm
- Stroke
- Cerebrovascular accident
- Neuromuscular disorders (e.g., ALS, MS, Parkinson's Disease)
- Dementia:

Patients with advanced dementia are offered quality-of-life diets; they risk injury with multiple insertion related to self-extubation of feeding tubes. Enteral feeding for end-stage dementia is controversial. Common reasons to initiate enteral feedings in these patients include prolonging survival, improving quality of life, preventing pressure ulcers, and palliative care. A review of the literature reveals, however, that patients with dementia who have enteral tubes are more likely to be restrained and continue to experience weight loss and poor nutrition. Their rate of survival is not improved, and there is no evidence of improved quality of life or decrease in pressure ulcers (Sampson, Candy

& Jones, 2009). Accumulating evidence indicates that negative effects of tube feeding may outweigh potential benefits in individuals with advanced dementia.

- Myopathy
- Parkinson's disease

Gastrointestinal Disorders

- Enterocutaneous fistula
- Inflammatory bowel disease
- Mild pancreatitis

Other situations

Respiratory Failure With Prolonged Intubation Inadequate Oral Intake

- Continuous feedings
- Supine positioning

A 30-degree elevation is recommended when possible for supine patients to reduce their risk of aspiration and, if intubated, prevent ventilator associated pneumonia (Metheny, 2006).

- Supine position is an indication for enteral feeding. Enteral feedings may be provided at the same rate as in the prone position, since they are likely to have the same residual in either position (Ellett, 2006).
- Cerebral vascular accident
- Local trauma
- Anorexia nervosa
- Difficulty chewing and swallowing
- Severe depression

► SKILL 42-3 Inserting a Small-Bore Nasoenteric or Oral Tube for Enteral Feeding

Delegation Considerations

At most Canadian institutions, the insertion of a sump naso/orogastric tube without stylet is an advanced nursing competency, requiring one-time certification. The insertion of a silastic feeding tube with stylet is considered a delegated medical function requiring yearly recertification. For this reason, this skill should not be delegated to unregulated care providers or those without a certified competency.

Equipment

- Nasogastric or nasointestinal (orogastric or orointestinal) tube (8- to 12-Fr) with guide wire or stylet
- Stethoscope
- 60 mL or larger Luer-Lok or catheter-tip syringe
- Entriflex nasogastric feeding tubes with safe enteral connections. (This weighted polyurethane feeding tube is designed for nasogastric and naso duodenal feeding with a slimmer lighter weighted tip for easier insertion. The feeding port is incompatible with Luer-Lok or IV connections, reducing the risk of accidental connection or inadvertent administration of IV intended medications through the feeding tube, a practice started in Great Britain and the United States to address the JCAHO [2006] Tubing Misconnections Sentinel Alert.)
- Hypoallergenic tape and tincture of benzoin or tube fixation device
- Scissors
- pH indicator strip (scale 0.0 to 11.0)
- Medication cup or container for aspirated fluid
- Glass of water and straw (not required for intubated patients)
- Water-soluble lubricant
- Emesis basin
- Absorbent pad
- Facial tissues
- Disposable gloves (multiple pairs needed)
- Suction equipment in case of aspiration
- Penlight to check placement of nasopharynx
- Tongue blade
- Disposable tape measure
- Felt-tip marker

► SKILL 42-3 Inserting a Small-Bore Nasoenteric or Oral Tube for Enteral Feeding—cont'd

Procedure

STEPS

1. Assess patient's need for enteral tube feeding: NPO (nothing by mouth) status, functional gastrointestinal tract, inability to ingest sufficient nutrients.
 - A. Review physician's order for insertion of tube and enteral feeding schedule.
2. Explain procedure to patient.
3. Assess patency of nares. Have patient close each nostril alternately and breathe. Examine each naris for patency and skin breakdown.
4. Assess the gag reflex by placing a tongue blade in patient's mouth, touching uvula to induce a gag response.

RATIONALE

- Identifying patients who need tube feedings before they become nutritionally depleted may help to prevent complications related to malnutrition.
- Procedures and tube feedings require a physician's order.
- Patient can cooperate with the process.
- Nares may be obstructed or irritated, or a septal defect may be present.
- This activity assesses ability to swallow and determines whether the patient is at risk for aspiration.

Critical Decision Point: Patients with impaired level of consciousness, or who are intubated and sedated, may also have impaired gag reflex, and their risk of aspiration is increased during this type of procedure and subsequent tube feedings. For patients who are intubated, sedated, or too ill to participate in the procedure, ensure that the patient's head is *tilted toward* the chest for enteral feeding tube insertion.

5. Review patient's medical history for nasal problems (e.g., nosebleeds, oral or facial surgery, anticoagulation therapy, history of aspiration).
 6. Perform hand hygiene.
 7. Auscultate abdomen for bowel sounds.
 8. Explain procedure to patient and how to communicate during insertion by raising index finger to indicate gagging or discomfort.
 9. Stand on same side of bed as naris for insertion, and assist patient to high Fowler's position unless contraindicated. Place pillow behind patient's head and shoulders.
 10. Place absorbent pad over patient's chest. Keep facial tissues within reach.
 11. Determine length of tube to be inserted and mark with tape:
 - A. Traditional method for placing the tube to the stomach: Measure distance from tip of nose to earlobe and then to xiphoid process of sternum (see Step 11A illustration).
- Nasoenteral tubes are contraindicated in patients with recent nasal surgery, facial traumas, nosebleeds, surgical procedures requiring a transsphenoid approach (e.g., to remove pituitary tumours) or receiving anticoagulation therapy (Metheny, 2002).
 - Hand hygiene reduces transfer of microorganisms.
 - Absence of bowel sounds may indicate decreased or absent peristalsis and increased risk for aspiration or abdominal distension.
 - Explanations reduce anxiety and help patient assist in insertion.
 - These actions facilitate manipulation of tube. Fowler's position reduces risk of aspiration and promotes effective swallowing.
 - Pad prevents soiling of gown. Insertion of tube may cause patient's eyes to tear.
 - Length approximates distance from nose to stomach for 98% of patients. For duodenal or jejunal placement, an additional 20 to 30 cm is required.

Step 11A Length of tube to be inserted is equal to distance from tip of nose to earlobe to xiphoid process.

If placing the tube to small bowel (duodenum), follow agency-specific protocol; for example, the administration of 10 mg metoclopramide as a bowel motility agent, turning patient on right side, and injecting 200 cc of air to inflate the stomach.

Continued

► SKILL 42-3 Inserting a Small-Bore Nasoenteric or Oral Tube for Enteral Feeding—cont'd

12. Prepare nasogastric or nasointestinal tube for insertion according to manufacturer recommendation:
 - A. Plastic tubes should *not* be iced.
 13. Perform hand hygiene and put on gloves.
 - A. If long-term tube, inject 10 mL of water from 30 mL or larger catheter-tip syringe into the tube and insert stylet/guide wire.
 - B. Make certain that guide wire is securely positioned against weighted tip and that connections are snugly fitted together.
 14. Cut tape 10 cm long or prepare tube fixation device. Split one end of tape lengthwise 5 cm.
 15. Dip tube with surface lubricant into glass of water. If tube is not prelubricated, use water-soluble lubricant.
 16. Insert tube through nostril to back of throat (posterior nasopharynx). Aim back and down toward ear.
 17. Have patient tilt head toward chest after tube has passed through nasopharynx.
- Tubes that are iced become stiff and inflexible, causing trauma to mucous membranes.
 - Hygiene and gloves reduce transmission of microorganisms.
 - Water releases a mechanism in the tip of the tube holding the guide wire in place to enable the guide wire to be removed following tube insertion.
 - Secure positioning and snug-fitting connections promote smooth passage of tube into gastrointestinal tract. Improperly positioned stylet can induce serious trauma (i.e., tracheal perforation, pneumothorax).
 - Tape is used to anchor tubing after insertion.
 - Activates lubricant to facilitate passage of tube into naris to gastrointestinal tract.
 - Natural contour facilitates passage of tube into gastrointestinal tract and reduces gagging by patient.
 - Tilting head forward closes off glottis and reduces risk of tube entering trachea. This technique is also used in patients who are intubated and sedated.

Critical Decision Point: Encourage a patient who is alert and communicating to swallow by giving small sips of water or ice chips when possible. For patients who are intubated and sedated, or are not able to participate in the procedure, tilt patient's head toward the chest. Advance tube as patient swallows or as patient's head is tilted toward chest. Rotate tube 180 degrees while inserting.

18. Emphasize the need to mouth-breathe and swallow during the procedure (when possible).
 19. When tip of tube reaches the carina (about 25 cm in an adult), stop insertion, hold end of tube near your ear, and listen for air exchange from the distal portion of the tube.
 20. Advance tube each time patient swallows until desired length has been passed.
- Mouth-breathing and swallowing facilitate passage of tube and alleviate patient's fear during the procedure.
 - **If air is heard, the tube could be in the respiratory tract; remove tube and start over. This listening step should never be used to verify tube placement** (Metheny, 2006).
 - Advancing tube while patient swallows reduces discomfort and trauma to patient.

Critical Decision Point: Do not force tube insertion. If resistance is met or patient starts to cough, choke, or become cyanotic, stop advancing the tube and pull tube back. It is important to note that heavily sedated, comatose, or paralyzed patients may not exhibit a cough or gag reflex during insertion and so this should not be used as the sole method of determining improper tube placement. It is also possible to slip a small-bore feeding tube into the trachea down past an endotracheal tube without loss of oxygenation; therefore, X-ray is the definitive step in determining tube placement.

21. Check for position of tube in back of patient's throat with penlight and tongue blade.
 22. Perform measures to verify placement of tube, once desired length has been passed. Secure tube before X-ray examination, because it may become dislodged during procedure.
- Tube may be coiled, kinked, or entering trachea. (Withdraw tube immediately if tube is coiled, respiratory status of patient changes, or patient begins to cough and skin colour changes. If distress is not present, withdraw tube fully and retry. Note whether tube was kinked; if so, it is likely to kink again in the same place.)
 - Tube placement must be verified by X-ray examination before enteral feedings are initiated. Another test that can be done at the bedside to ensure ongoing placement is to measure pH of any aspirated gastric fluids.

Critical Decision Point: Auscultation is **not** a reliable method for verification of tube placement because a tube inadvertently placed in the lungs, pharynx, or esophagus can transmit a sound similar to that of air entering the stomach (Metheny, 2006; Richardson, et al., 2006; Wagner, 2004).

23. After gastric aspirates are obtained (see Box 42-4), anchor tube to patient's nose and avoid pressure on nares. Mark exit site with indelible ink. Select one of the following options:
 - A. Apply tape.
 - (1) Apply tincture of benzoin or other skin adhesive on tip of patient's nose and tube and allow it to become "tacky."
- A properly secured tube allows the patient more mobility and prevents trauma to nasal mucosa. Mark tube at tip of naris; measure from line to end of tube; tape and secure to maintain position.
 - Skin adhesive helps tape adhere better and protects patient's skin.

► SKILL 42-3 Inserting a Small-Bore Nasoenteric or Oral Tube for Enteral Feeding—cont'd

- (2) Place the intact end of tape over bridge of patient's nose. Wrap each of the 5 cm strips around tube as it exits nose. Change position of tube at naris every 8 hours (q8h) (see Step 23A(2) illustration).

B. Apply tube fixation device, using shaped adhesive patch.

- (1) Apply wide end of patch to bridge of nose.
(2) Slip connector around tube as it exits nose (see Step 23B(2) illustration).

Step 23A(2) Wrapping tape to anchor nasoenteral tube.

Step 23B(2) Slipping connector around feeding tube.

24. A second anchoring of tube against cheek with gauze and transparent dressing may be advised (Linford & McGinnisi, 2011). Do not allow tube to rest over bony points.
25. For intestinal placement, position patient on right side when possible until correct placement has been verified radiologically. Remove gloves. Perform hand hygiene, and assist patient to a comfortable position.

- Securing tape to nares prevents tissue necrosis. Changing tube position avoids erosion of naris.
- Fixation device secures tube and reduces friction on nares.

- Fastening the tube this way helps to prevent the tube from being pulled by confused patients and avoids pressure points.
- Positioning patient on right side promotes passage of the tube into the small intestine (duodenum or jejunum).

Critical Decision Point: Leave stylet/guide wire in place until correct position is ensured by X-ray film or check agency policy that states how long you can leave the wire or stylet in place if the X-ray or interpretation is delayed. Never attempt to reinsert partially or fully removed stylet/guide wire while feeding tube is in place.

Clinically sound judgement is always required for nasogastric insertion and placement verification. Cortrak is a device used to place small-bore tubes in an effort to improve efficiency and reduce patient discomfort by checking the placement as the tube is inserted at bedside. This reduces the need to verify placement. Cortrak involves computer technology to guide clinicians in the placement of nasoenteric feeding tubes. The device aids feeding tube placement by showing the relative location of the feeding tube tip as it descends into the tract. The tip of the feeding tube stylet has an electromagnetic transmitter. A receiver unit is placed on the patient's xiphoid during the procedure, to acquire the signal (Lei et al., 2007; Mackay et al., 2009).

26. Obtain X-ray film of abdomen.
27. Perform hand hygiene, apply clean gloves, and administer oral hygiene (see Chapter 37). Cleanse tubing at nostril.
28. Remove gloves, dispose of equipment, and perform hand hygiene.
29. Inspect patient's naris and oropharynx for any irritation after insertion.
30. Ask patient whether he or she feels comfortable.
31. Observe patient for any difficulty breathing or for coughing or gagging.
32. Auscultate lung sounds.

- Placement of tube is verified by X-ray examination (Ellett, 2006; Metheny & Meert, 2004).
- Oral hygiene promotes patient comfort and integrity of oral mucous membranes.
- These actions reduce transmission of microorganisms.
- If tube insertion was difficult, irritation of naris or oropharynx may have occurred.
- Patient's level of comfort is evaluated. (This may be a challenge if a language barrier exists or if the patient has dementia or is confused.)
- Improper position of the tube may cause these symptoms or increase symptoms in patients who have heart failure, pneumonia, asthma, and other cardiac or respiratory conditions.
- Abnormal lung sounds can be an early sign of aspiration.

Continued

► SKILL 42-3 Inserting a Small-Bore Nasoenteric or Oral Tube for Enteral Feeding—cont'd

Unexpected Outcomes

Aspiration of stomach contents into the respiratory tract (immediate response), evidenced by coughing, dyspnea, cyanosis, auscultation of crackles or wheezes

Aspiration of stomach contents into respiratory tract (delayed response), evidenced by dyspnea, fever, auscultation of crackles or wheezes

Development of bacterial aspiration pneumonia from contaminated saliva for patients NPO or being fed enterally.

Displacement of feeding tube to another site (e.g., from duodenum to stomach, which may occur when patient coughs or vomits)

Related Interventions

- Position patient on side.
- Suction nasotracheally and orotracheally.
- Consult physician immediately to order chest X-ray examination.
- Consult physician to obtain order for chest X-ray film.
- Prepare for possible initiation of antibiotics.
- Limited oral hydration leads to dry mouth and increased concentration of oral bacteria. It is imperative that scrupulous oral hygiene be maintained for these individuals, which includes using a soft tooth brush to clean teeth, gums, roof of mouth, and cheeks. Patients and their families must be counselled regarding this risk for those who are discharged home or maintain self-care (Canadian Stroke Network Best Practices, 2010).
- Confirm that mark on tube (made at initial insertion) is at exit site (if tube is moved, mark at new exit site).
- Remeasure distance from naris to tip, and compare with baseline measurement from insertion.
- Aspirate gastrointestinal contents and measure pH (Richardson et al., 2006).
- Discuss findings with physician.
- Reconfirm placement by X-ray film (optional).
- If tube is displaced, prepare to remove displaced tube, and insert and verify placement of new tube.
- If there is a question of aspiration, obtain chest X-ray film.

Critical Decision Point: To prevent clogging of feeding tube in relation to feedings, flush feeding tube with tap water (Best, 2009) after checking residual volume, after intermittent feeding, every four hours during continuous feedings, and before and after administration of medications. On average, use 15 to 30 mL or more of water for flushing. The amount of water required varies with the individual length of tube. Try to find an alternative route for medication administration when small-bore tubes (especially the temporary nasogastric silastic tubes) are used because they frequently clog.

Clogging of feeding tube

- To prevent feeding tube clogging that results from medication, use liquid forms of medication whenever possible. When the solid form of dosage is used, make sure tablets can be crushed and that there is no contraindication to crushing them (i.e., sustained-release cardiac meds should *not* be crushed as they will adversely affect the patient's hemodynamic status [HR and BP]) and capsules can be opened; dissolve tablets or capsules well, and administer each medication separately (Williams, 2008).
- Aspirate gastric contents with 60 mL syringe to assess patency of tube.
- Irrigate tube with water.
- Notify physician and prepare to administer pancrelipase upon physician order or standing protocol. Pancrelipase dissolves foodstuff but is ineffective in dissolving pill particles.
- Attempt to clear tube with pancrelipase using a 50 to 60mL syringe. Do *not* use a small-barrel syringe (i.e., 20 cm or less) because smaller syringes have greater psi (pounds per square inch) and injection of air or liquid under high pressure (above 40 psi) may cause tube rupture (Grant & Martin, 2000).
- Provide hygiene, and remove and replace tube. (Note: This action requires a physician's order.)
- Consider removing tube and inserting it into the other naris (physician order required).

Irritation of naris and nasal mucosa

Recording and Reporting

- Record and report type and size of tube placed, location of distal tip of tube (mark and measure), patient's tolerance of procedure, pH value, and confirmation of tube position by X-ray examination.

► SKILL 42-4 Administering Enteral Feedings via Nasoenteric Tube

Delegation Considerations

Administration of enteral tube feeding via nasoenteric tube is an institution-specific procedure that may or may not be delegated to unregulated care providers (UCPs) after the nurse verifies tube placement. The nurse is responsible for patient assessment. Depending on the institution's protocol, the nurse directs the UCPs to

- Ensure that the patient is sitting upright in a chair or in bed
- Infuse the feeding slowly
- Report any difficulty infusing the feeding or any discomfort voiced by the patient

Equipment

- Disposable feeding bag and tubing or ready-to-hang system
- 30 mL or larger Luer-Lok or catheter-tip syringe
- Stethoscope
- pH indicator strip (scale 0 to 14)
- Infusion pump (required for intestinal feedings): use pump designed for tube feedings
- Prescribed enteral feedings
- Disposable gloves
- Equipment to obtain blood glucose by fingerstick

Procedure

STEPS

1. Assess patient's need for enteral tube feedings: impaired swallowing, tracheostomy, decreased level of consciousness, head or neck surgery, facial trauma, surgical procedures involving upper alimentary canal.
2. Evaluate patient's nutritional status (see Table 42-6). Obtain baseline weight and laboratory values (e.g., albumin, transferrin, prealbumin). Assess patient for fluid volume excess or deficit, electrolyte abnormalities, and metabolic abnormalities, such as hyperglycemia.
3. Verify physician's order for formula, rate, route, and frequency and for laboratory data and bedside assessments, such as fingerstick blood glucose measurement.
4. Explain procedure to patient.
5. Perform hand hygiene.
6. Auscultate for bowel sounds before feeding.
7. Prepare feeding container to administer formula:
 - A. Check expiration date on formula and integrity of container.
 - B. Have tube feeding formula at room temperature.
 - C. Perform hand hygiene and apply gloves.
 - D. Shake formula container well, and fill feeding container with formula (see Step 7D illustration). Open stopcock on tubing and fill with formula to remove air.

Step 7D Pouring formula into feeding container.

RATIONALE

- Identify patients who need tube feedings before they become nutritionally depleted.
- Enteral feedings are intended to restore or maintain a patient's nutritional status. Fluid volume assessment provides objective data to measure effectiveness of feedings.
- Tube feedings, laboratory tests, and bedside tests must be ordered by the physician.
- Well-informed patients are cooperative and comfortable.
- Hand hygiene reduces transmission of microorganisms.
- Absence of bowel sounds may indicate decreased ability of gastrointestinal tract to digest or absorb nutrients.
- Tube feedings administered within the designated shelf life from a container without cracks or breaks reduces the patient's risk of acquiring tube feeding–borne gastrointestinal infections.
- Cold formula may cause gastric cramping and discomfort because the liquid is not warmed by the mouth and esophagus.
- Filling the tubing with formula prevents excess air from entering.
- Tubing must be free of contamination in order to prevent bacterial growth.

Continued

► SKILL 42-4 Administering Enteral Feedings via Nasoenteric Tube—cont'd

- E. Connect tubing to container as needed, or prepare ready-to-hang container.

Critical Decision Point: Tube feedings are infused by feeding pumps and the tubes do not fit intravenous (IV) pump.

8. For intermittent feeding, have syringe ready, and ensure formula is at room temperature.
9. Place patient in high Fowler's position, or elevate head of bed at least 45 degrees.
10. Verify tube placement (see Box 42-13). Consider the results from pH testing together with the aspirate's appearance.
 - Cold formula may cause gastric cramping.
 - Elevating the patient's head helps prevent aspiration.
 - On occasion, colour alone may differentiate gastric from intestinal placement. Because most intestinal aspirates are stained by bile to a distinct yellow colour and most gastric aspirates are not so stained, the difference may be distinguished. However, colour differences among the stomach and intestine are often difficult to discern, and the aspirate's colour must be considered in combination with other assessment data (Richardson et al., 2006).
 - pH ≤ 4 confirms gastric aspirate in adults while pH ≤ 5 confirms gastric aspirate in infants and young children (Gilbertson et al., 2011).
11. Check pH of aspirate; confirm measurement of length of tube from naris to tip of connection port; ensure original mark is in the same position.

Critical Decision Point: Auscultation is not considered a reliable method for verification of placement of tube because a tube inadvertently placed in lungs, pharynx, or esophagus can transmit sound similar to that of air entering stomach (Metheny & Meert, 2004; Serna & McCarthy, 2006).

12. Check for gastric residual.
 - A. Draw 30 mL of air with syringe. Connect to end of feeding tube. Flush tube with air.
 - B. Pull back evenly to aspirate gastric contents (see Step 12B illustration).

Step 12B Check for gastric residual (small-bore tube).

Please note that if checking for gastric residual when a small-bore tube is in place, consult agency policy. Aspirating flexible small-bore tubes is controversial as they tend to collapse more easily, making assessment of residuals inaccurate and can cause precipitates when mixed with high pH feedings and cause clogging (Kenny & Goodman, 2010). Remember that tube location is important. A tube in the small bowel would have ongoing secretions and much more residual and therefore checking residuals would not be necessary.

- C. Return aspirated contents to stomach if specified by agency policy.
 - Return of aspirate is also a controversial topic that requires further research. According to Booker et al. (2000), return of aspirate prevents fluid and electrolyte imbalance, although tube occlusions occur more frequently when aspirate is returned. In a random control trial, Juvé-Udina et al. (2009) found no differences in fluid balance or serum electrolyte outcomes and no tube clogging for those to whom gastric aspirate was returned (intervention group). The control group, however, suffered more distress, suggesting that returning the gastric aspirate could help maintain gastric residual volume at closer physiological levels.

► SKILL 42-4 Administering Enteral Feedings via Nasoenteric Tube—cont'd

video

13. Flush tubing with 30 to 50 mL of tap water at room temperature (Best, 2009).

14. Label feeding tube bag. Complete and post nutrition label on bag to indicate type of formula, rate, time, and date.

15. Initiate feeding:

A. Syringe or intermittent feeding:

- (1) Pinch proximal end of the feeding tube.
- (2) Remove plunger from syringe and attach barrel of syringe to end of tube.
- (3) Fill syringe with measured amount of formula (see Step 15A[3] illustration). Release tube and hold syringe high enough to allow it to empty gradually by gravity, and refill; repeat until prescribed amount has been delivered to the patient.
- (4) If feeding bag is used, hang feeding bag on an IV pole (see Step 15A[4] illustration). Fill bag with prescribed amount of formula, and allow bag to empty gradually over at least 30 minutes, depending on the amount of feeding.

• Ensure tube is clear and patent.

• Pinching prevents air from entering patient's stomach.

• Gradual emptying of tube feeding by gravity from syringe or feeding bag reduces risk of abdominal discomfort, vomiting, or diarrhea induced by bolus or too-rapid infusion of tube feedings.

• A feeding pump is used to infuse the formula. An intravenous pump must not be used for enteral feedings.

Step 15A(3) Fill syringe with formula.

Step 15A(4) Administration via feeding bag.

(5) Document tube assessment for placement, formula infusing, and infusion rate; elevate head of bed at least 45 degrees.

B. Continuous-drip method (see Step 15B illustration):

- (1) Prime and hang feeding bag and tubing.
- (2) Connect distal end of tubing to the proximal end of the feeding tube.
- (3) Connect tubing through infusion pump and set rate (see illustration).
- (4) Do *not* hang any longer than a four-hour supply to decrease risk of food spoilage potentially resulting in GI irritation or infection.

• Continuous feeding method is designed to deliver a prescribed hourly rate of feeding. This method reduces risk of abdominal discomfort. **Patients who receive continuous drip feedings should have residuals checked every four hours and tube placement verified.** Tube placement verification is difficult with continuous feeding because PH of formula affects the stomach pH. Measurement of gastric residuals every four hours is prudent in critically ill patients (Bankhead et al., 2009).

Step 15B Prime and connect tubing through infusion pump.

16. Advance the rate of tube feeding gradually (see Box 42-11).

• Tube feedings should be advanced gradually to prevent diarrhea and gastric intolerance to formula.

Continued

► SKILL 42-4 Administering Enteral Feedings via Nasoenteric Tube—cont'd

17. After intermittent infusion or at end of continuous infusion, flush nasoenteral tubing with water. On average, 30 mL of water is used, but the amount can vary from 10 mL to over 30 mL. Repeat every four to six hours. Remove gloves and perform hand hygiene.

- Flushing maintains patency of feeding tube and provides patient with a source of water to help maintain fluid and electrolyte balance.

Critical Decision Point: It may be necessary to consult with a dietitian to recommend a total free water requirement per day. This avoids the potential of fluid overload.

18. When tube feedings are not being administered (e.g., they may be held prior to tests or procedures such as extubation, cap or clamp the proximal end of the feeding tube).
19. Rinse bag and tubing with water whenever feedings are interrupted or q 8 h.
20. Change bag and tubing every 24 hours.
21. Measure amount of aspirate (residual) every 8 to 12 hours.
22. **Monitor fingerstick blood glucose level every 6 hours until maximum administration rate is reached and maintained for 24 hours.**
23. Monitor intake and output every 8 hours and compute 24-hour totals.
24. Weigh patient daily until maximum administration rate is reached and maintained for 24 hours; then weigh patient three times per week.
25. Observe patient's respiratory status.
26. Observe return of normal laboratory values.

- Closing the end of the tube prevents air from entering stomach between feedings and prevents contamination.
- Rinsing bag and tubing clears old tube formula and reduces bacterial growth.
- Changing bag and tubing reduces patient's exposure to bacterial growth occurring in those items.
- These measurements help evaluate tolerance of tube feeding.
- These levels alert the nurse to patient's tolerance of glucose. Remember that if feedings are stopped, monitor for any drop in glucose level—especially if patient is on an insulin therapy.
- Intake and output are indications of fluid balance or fluid volume excess or deficit.
- Weight gain is an indicator of improved nutritional status; however, sudden gain of more than 1 kg in 24 hours usually indicates fluid retention.
- Increased respiratory rate may indicate aspiration of tube feeding.
- Improving laboratory values (e.g., albumin, transferrin, and prealbumin) indicate an improved nutritional status.

Unexpected Outcomes (in addition to those identified in Skill 42-1)

Gastric residual exceeding 200 to 500 mL (Bankhead et al., 2009) (see Agency Policy)

Diarrhea three times or more in 24 hours

Nausea and vomiting

Related Interventions

- Withhold feeding.
- Notify physician. The North American Summit on Aspiration in the Critically Ill Patient has suggested that risk reduction be initiated because aspiration occurs significantly more often when gastric residual volumes are high (Bankhead et al., 2009; Metheny et al., 2008).
- Maintain patient in semi-Fowler's position, or have head of bed elevated at least 30 to 45 degrees.
- Perform physical assessment.
- Assess glycemic control.
- Minimize sedation.
- Consider administering motility agent.
- For residual exceeding 150 mL: **Recheck residual in one hour** (Metheny et al., 2008).
- Notify physician.
- Confer with dietitian.
- Institute skin-care measures.
- Look for other causes of the diarrhea (e.g., antibiotics). Consider change in antibiotics only for patients receiving antibiotics.
- Notify physician.
- Check patency of tube.
- Aspirate for residual.
- Auscultate for bowel sounds.

Recording and Reporting

- Record amount and type of feeding and patient's response to tube feeding, patency of tube, and any side effects.
- Report patient's tolerance and adverse effects.

Home Care Considerations

- Teach patient or primary caregiver how to determine correct placement of feeding tube using pH strips.
- Inform patient or primary caregiver of signs associated with pulmonary aspiration and delayed gastric emptying.
- Describe signs and symptoms associated with feeding tube complications, and advise when to call physician.

► SKILL 42-5 Administering Enteral Feedings via Gastrostomy or Jejunostomy Tube**Delegation Considerations**

Administration of enteral tube feeding via a gastrostomy or jejunostomy tube is a procedure that—depending on agency policy—can be delegated to an unregulated care provider (UCP) after the nurse verifies tube placement. UCPs should never test the position of the tube or give the first dose of a tube feeding.

- Ensure that the patient is sitting upright in a chair or in bed, and instruct the UCP to infuse the feeding slowly.
- Instruct the UCP to report any difficulty infusing the feeding or any discomfort voiced by the patient.

Procedure**STEPS**

1. Assess patient's need for enteral tube feedings (see Skill 42-3 and Skill 42-4): impaired swallowing, decreased level of consciousness, surgical procedures involving upper alimentary tract, need for long-term enteral nutrition.
2. Obtain baseline weight and laboratory values (blood glucose, albumin, transferrin, prealbumin).
3. Verify physician's order for formula, rate, route, and frequency.
4. Perform hand hygiene.
5. Explain procedure to patient.
6. **Auscultate for bowel sounds before feeding. Consult physician if bowel sounds are absent.**
7. Assess gastrostomy or jejunostomy site for breakdown, irritation, or drainage.
8. Perform hand hygiene and apply gloves.
9. Prepare feeding container to administer formula:
 - A. Have tube feeding formula at room temperature.
 - B. Connect tubing to container as needed, or prepare ready-to-hang bag.
 - C. Shake formula well. Fill container and tubing with formula.
10. For intermittent feeding, have syringe ready and ensure formula is at room temperature.
11. Elevate head of bed 30 to 45 degrees.
12. Apply gloves and verify tube placement.
 - A. Gastrostomy tube: Attach syringe and aspirate gastric secretions; observe their appearance and check pH. Return aspirated contents to stomach unless the volume exceeds 100 mL or specified amount based on patient's age. If the volume is greater than 100 mL or the specified amount on several consecutive occasions, check agency policy regarding stopping the feeding and notifying the physician.
 - B. Jejunostomy tube: Aspirate intestinal secretions, observe their appearance, and check pH.
13. Flush with 30 mL of room temperature tap water.

Equipment

- Disposable feeding container or ready-to-hang bag.
- 30 mL or larger Luer-Lok or catheter-tip syringe
- Formula
- Infusion pump: Use pump designed for tube feedings
- pH indicator strips (scale 0 to 14)
- Medication cup or container for aspirated fluid
- Stethoscope
- Disposable gloves
- Equipment to obtain blood glucose by fingerstick

RATIONALE

- This assessment identifies patients who need tube feedings before they become nutritionally depleted. Enteral feeding preserves the function and mass of the gut, promotes wound healing, diminishes hypermetabolism in burn injuries, and may decrease infection in critically ill patients (Ellett, 2006; Pearce & Duncan, 2002).
- Enteral feedings are intended to restore or maintain nutritional status. Baseline weight and laboratory values provide objective data to measure effectiveness of feedings.
- Tube feedings must be ordered by a physician.
- Hygiene reduces transmission of microorganisms.
- Well-informed patients are more cooperative and more at ease than patients who are ill-informed.
- Absence of bowel sounds may indicate decrease in or absence of peristalsis and increased risk of aspiration or abdominal distension.
- Infection, pressure from tube, or drainage of gastric secretions can cause skin breakdown.
- Cold formula may cause gastric cramping and discomfort because the liquid is not warmed by mouth and esophagus.
- Tubing must be free of contamination in order to prevent bacterial growth.
- Placement of formula through tubing prevents excess air from entering gastrointestinal tract.
- Cold formula may cause gastric cramping.
- Elevating patient's head helps prevent chance of aspiration.
- Fluid from gastric tube of patient who has fasted for at least four hours usually has a pH of 1 to 4, especially when patient is not receiving a gastric-acid inhibitor. Continuous administration of tube feedings may elevate pH (Metheny, 2006). Gastric residual indicates whether gastric emptying is delayed. Delayed gastric emptying for a gastrostomy tube may be indicated by 100 mL or more remaining in patient's stomach from previous feeding (Bourgault et al., 2007).
- Presence of intestinal fluid indicates that the end of the tube is in the small intestine (i.e., the duodenum or jejunum). In general, the intestinal residual is very small (10 mL or less). If fluid appears acidic on pH test, if fluid looks like gastric fluid, or if the residual volume is large (more than 10 mL), displacement of the tube into the stomach may have occurred.

Continued

► SKILL 42-5 Administering Enteral Feedings via Gastrostomy or Jejunostomy Tube—cont'd**14. Initiate feedings:****A. Syringe feedings:**

- (1) Pinch proximal end of gastrostomy or jejunostomy tube.
- (2) Remove plunger and attach barrel of syringe to end of tube; then fill syringe with formula.
- (3) Release tube and elevate syringe. Allow syringe to empty gradually by gravity. Refill until prescribed amount has been delivered to patient.

B. Continuous drip method:

- (1) Verify that volume in container is sufficient for length of feeding (four to eight hours, check manufacturer's recommendations).
- (2) Hang container on IV pole, and clear tubing of air.
- (3) Thread tubing into pump according to manufacturer's directions.
- (4) Connect tubing to end of gastrostomy or jejunostomy tube.
- (5) Begin infusion at prescribed rate.

15. Administer water via feeding tube as ordered with or between feedings.**16. Flush tube with 30 mL of water every four to six hours and before and after administering medications via feeding tube.****17. When tube feedings are not being administered, cap or clamp the proximal end of the gastrostomy or jejunostomy tube.****18. Rinse container and tubing with water after all intermittent feedings.****19. Assess skin around tube exit site. Before site has healed, clean with normal saline. The skin around the tube should be cleansed daily with warm water and mild soap once site has healed. Fully healed tubing exit site is left open to air. Prior to healing, a small precut gauze dressing may be applied to exit site and secured with tape. The dressing is assessed for drainage and changed daily and as needed. If patient received nasogastric feedings before tube insertion and then undergoes a procedure, tube is not used for first four to six hours after procedure. (Patient will be NPO status the night before the procedure. Postprocedure documentation—as per agency policy—will indicate when to use tube.) Feeding will resume at previous nasogastric rates once it is safe to begin feeding.****20. Dispose of supplies, and perform hand hygiene.****21. Evaluate patient's tolerance to tube feeding. Measure the amount of aspirate q 8 to 12 hours.**

- Gastrostomy and jejunostomy feedings are usually given continuously to ensure proper absorption. However, initial feedings may be given by bolus to assess patient's tolerance to formula. See Box 42-11 for guidelines to advance enteral feedings.
- Pinching prevents excessive air from entering the patient's stomach and prevents the leaking of gastric contents.
- Gradual administration of tube feedings by gravity reduces the risk of diarrhea induced by bolus tube feedings.
- Continuous-feeding method is designed to deliver a prescribed hourly rate of feeding. This method reduces the risk of diarrhea and risk of abdominal discomfort. Patients who receive continuous-drip feedings should have residuals checked every four hours and tube placement verified. Measurement of gastric residuals every four hours is prudent in critically ill patients (Bankhead et al., 2009).
- Over the long term, you must continue assessing residuals at least every six hours for patients considered at risk for aspiration. Gastric residual volumes can be reduced to every six to eight hours in noncritically ill patients after the first 48 hours of being fed (Bankhead et al., 2009).
- Hanging the container allows for gravity-based flow of formula, which prevents accumulation of air in the patient's stomach.
- Water helps patients maintain fluid and electrolyte balance.
- Flushing maintains patency of tube and provides patient with some free water. Small jejunal tubes are prone to clogging and are difficult to replace (Pearce & Duncan, 2002).
- Closing the end of the tube prevents excess air from entering the gastrointestinal tract between feedings and prevents leakage of gastric contents.
- Rinsing clears formula from tubing and reduces bacterial growth in container and tubing. The container and tubing should be changed every 24 hours.
- Report any drainage, redness, swelling, or displacement of the tube to the physician. Leakage of gastric drainage may cause skin irritation.
- Postprocedure monitoring is performed to check for bleeding.
- Hygiene prevents transmission of microorganisms.
- Measurements help evaluate tolerance of tube feeding.

► SKILL 42-5 Administering Enteral Feedings via Gastrostomy or Jejunostomy Tube—cont'd

- 22. Monitor fingerstick blood glucose level every 6 hours until maximum administration rate is reached and maintained for 24 hours.
 - 23. Monitor intake and output every 24 hours.
 - 24. Weigh patient daily until maximum administration rate is reached and maintained for 24 hours; then weigh patient three times per week.
 - 25. Observe return of normal laboratory values.
 - 26. Inspect stoma site for signs of impaired skin integrity.
- Alerts nurse to patient's tolerance of glucose.
 - Intake and output are indications of fluid balance or fluid volume excess.
 - Weight gain is an indicator of improved nutritional status; however, a sudden gain of more than 1 kg in 24 hours usually indicates fluid retention.
 - Improving laboratory values (albumin, transferrin, prealbumin) indicate improved nutritional status.
 - Enteral tubes can cause pressure and excoriation at the stoma site. In addition, gastric secretions irritate patient's skin.

Unexpected Outcomes

Aspiration of formula when gastric emptying is delayed or formula is administered too rapidly and produces vomiting

Skin breakdown around gastrostomy or jejunostomy site

Related Interventions

- Position patient in side-lying position.
- Suction airway.
- Notify physician.
- Obtain chest X-ray film.
- Institute skin care practices.
- Use pressure relief measures around tube.
- Provide appropriate wound care (see Chapter 46).

Recording and Reporting

- Record amount and type of feeding and patient's response to tube feeding, patency of tube, stoma site, and skin integrity, and document any side effects.
- Report to incoming nursing staff type of feeding, status of feeding tube, patient's tolerance, and adverse effects.

Home Care Considerations**Teaching Patient or Primary Caregiver How to Determine Correct Placement of Feeding Tube**

- Aspirate and check pH.
- Measure tube length.

Signs Associated With Pulmonary Aspiration and Delayed Gastric Emptying

- Advise patient or primary caregiver to be alert for increased or laboured breathing.
- Instruct patient or caregiver to report shortness of breath.
- Instruct patient or caregiver to report enlarged or tender abdomen.
- Instruct patient or caregiver to be alert for residuals exceeding 200 mL (increased residuals may be related to aspiration) (Metheny et al., 2008).

Reinforcing Signs and Symptoms Associated With Feeding Tube Complications and When to Call Physician

- Shortness of breath
- Laboured breathing
- Cramping, vomiting
- Diarrhea two to three times per day
- Constipation
- Tube occlusion
- Tube length increase of 3 to 5 cm or dislodgement

Tube feedings are typically started at full strength at slow rates (Box 42-12). The hourly rate is increased every 12 to 24 hours if no signs of intolerance (nausea, cramping, vomiting, diarrhea) appear.

Studies have demonstrated a beneficial effect of enteral feedings in comparison with parenteral (intravenously administered) nutrition. Feeding by the enteral route may reduce sepsis, blunt the hypermetabolic response to trauma, and maintain intestinal structure and function (Gramlich et al., 2004). To remove the tube, use the following procedure (Box 42-13).

Preventing Complications

A serious complication associated with enteral feeding is aspiration of enteral formula into the tracheobronchial tree.

Aspiration of enteral formula into the lungs irritates the bronchial mucosa, resulting in decreased blood supply to affected pulmonary tissue (Metheny, 2006). This leads to necrotizing infection, pneumonia, and potential abscess formation. The high glucose content serves as a bacterial medium for growth, thereby promoting infection. Adult respiratory distress syndrome is also frequently associated with pulmonary aspiration. Common conditions that increase the risk of aspiration include coughing, nasotracheal suctioning, an artificial airway, decreased level of consciousness, and lying flat during and after feeding.

Researchers have investigated the problems associated with nasoenteral tube placement, type of feeding instilled, rate of feeding, and complications associated with tube feeding.

► BOX 42-12

Advancing the Rate of Tube Feeding

Intermittent

1. Start formula at ordered concentration.
2. If based on physician order and agency policy, infuse bolus of formula over at least 20 to 30 minutes via syringe or feeding container.
3. Begin feedings with no more than 150 to 250 mL at one time. Increase incrementally by 50 mL per feeding per day to achieve needed volume and calories in six to eight feedings. The amount of increase varies depending on age of patient and tolerance. Rates for pediatric patients may increase by 5 to 10 mL per 8 to 24 hours while rates for adults may be increased by 50 mL per feeding per day. (Note: Concentrated formulas at full strength may be infused at slower rates until tolerance is achieved.)

Continuous

1. Start formula at ordered concentration full strength for isotonic formulas; concentration of all nutrients in the formula is the same as the concentration of plasma—the fluid component of blood—at approximately 300 mOsm/kg water) or at ordered concentration. Usually hypertonic formulas are also started at full strength but at a slower rate because hypertonic formulas create a pressure gradient that draws water into the intestine and may cause diarrhea and cramping.
2. Begin infusion rate at designated rate.
3. Advance rate slowly (e.g., 10 to 20 mL/hour per day, depending on patient's age) to target rate if tolerated (tolerance indicated by absence of nausea and diarrhea and by low gastric residuals).

► BOX 42-13 Procedural Guideline

Discontinuing Enteral Feedings via Nasogastric Tube**Equipment:**

- Clean gloves, facial tissues, towel or absorbent pad, disposable bag

Procedure:

1. Check the physician's order to discontinue nasogastric tube.
2. Educate patient about what to expect during procedure:
 - A. Patient may experience irritation of nose and throat, as well as watering of the eyes.
 - B. Encourage patient to breathe out as the tube is being removed, to promote comfort and ease of removal.
3. Perform hand hygiene and apply gloves.
4. Assist patient to sit up in high Fowler's position, if possible (to protect patient from drainage). Encourage patient participation.
 - A. Place towel over patient's chest.
 - B. Provide tissues to patient.
5. Disconnect tube from pump and from patient's gown.
6. Ask patient to take a deep breath and exhale slowly; pinch tube and withdraw it slowly.
7. Provide oral care to patient; provide skin care around patient's nares.
8. Document procedure and total fluid balances.

Figure 42-11 Enteral tubes, small bore.

Small-bore feeding tubes create less discomfort for patients and are currently most often used (Figure 42-11). For adults, most of these tubes are 8 to 12 Fr and 91 to 109 cm long. A stylet is often used during insertion of a small-bore tube to stiffen it. The stylet is removed when the correct position of the feeding tube is confirmed.

At present, the most reliable method for verification of placement of small-bore feeding tubes is X-ray examination (Box 42-14). Measuring the pH of secretions withdrawn from the feeding tube may also help differentiate the location of the tube (Box 42-15). Patients who take acid inhibitor medications usually have an acidic pH value ranging from 4.0 (after four hours of fasting) to 6.0 (with continuous enteral nutrition infusion). In contrast, intestinal aspirate has a pH of 7.8 to 8.0. More precise indicators are needed to help differentiate the source of tube feeding aspirate (Ellett, 2006; Metheny, 2006).

Major complications of enteral nutrition are outlined in Table 42-8. Of special note, severely malnourished patients are at risk for electrolyte disturbances from **refeeding syndrome** (metabolic disturbances that occur as a result of reinstituting nutrition) because cations such as potassium, magnesium, and phosphate move intracellularly during enteral nutrition or parenteral nutrition therapy. There are also situations where enteral nutrition is not effective in nourishing the body and your role as a nurse is to support a patient in a different way. Box 42-16 describes a story of a nurse who learned that nourishing a person's soul is important.

Large-Bore Tube and Nasogastric or Orogastric Suctioning

Gastric decompression is the use of suction to drain the stomach to relieve blockage of the intestinal tract, to wash out stomach contents when a person has taken poisonous material, or after surgery (Dugas & Knor, 1995).

After surgery, the objectives for drainage are as follows:

- Reduce abdominal distension
- Speed the return of bowel function
- Reduce the chance of wound dehiscence and hernia

The two types of tubes most commonly used for gastric decompression are the Levine and Salem sump tube. The tubes are large: 16 to 18 Fr are commonly used and may be inserted through nares or orally if deemed necessary. Orogastric tubes are often placed in patients with facial fractures or sinusitis (Dugas & Knor, 1995). (See Skill 42-6 and Box 42-17.)

★ BOX 42-14 RESEARCH HIGHLIGHT

Accuracy in Determining Placement of Feeding Tubes

Research Focus

Two possible adverse outcomes of enteral nutrition are (1) accidental placement of a nasogastric feeding tube into the lung and (2) pulmonary aspiration of gastric contents.

Research Abstract

No one knows the precise incidence of accidental tube misplacements into the lung, but estimates of close to 5% have been cited. Patients at highest risk are those with a decreased level of consciousness; those who are confused, uncooperative, or agitated; those who have an endotracheal tube; those who have undergone recent extubation; and those with poor gag reflex. A feeding tube accidentally inserted into the lung may end in the tracheobronchial tree or may perforate into the pleural space. In either event, efforts are made to detect the misplacement before the introduction of tube feedings because inadvertent infusion of formula into the lung promotes tissue consolidation, pneumonia, and respiratory failure. The most accurate method for checking feeding tube placement is X-ray examination; the most effective nonradiological method is aspirating fluid from the feeding tube, measuring its pH, and describing its appearance. Although observing for respiratory distress is helpful in alert patients (especially when firm large-diameter tubes are used), it is of little benefit in those who have a decreased level of consciousness and when small-bore tubes are used. Risk factors for pulmonary aspiration in tube-fed patients include feeding into the stomach in the presence of gastric atony (which results in high gastric residual volumes), poor gag reflexes, mechanical ventilation, and flat positioning in bed. Bedside methods used to detect pulmonary aspiration are not well defined.

Evidence-Informed Practice

- Radiography is the most reliable method available to confirm correct feeding tube location, and radiographic verification is required in most acute care facilities when small-bore tubes are initially inserted.
- When the radiographic method is not feasible, a less reliable method involves testing the feeding tube aspirate's pH and observing its appearance. A properly obtained pH of 0 to 4 is a good indication of gastric placement; a pH of 6 or higher could indicate placement in the lung, intestine, or even the stomach, in which gastric pH is usually high. Intestinal fluid is usually bile-stained (dark golden yellow); in contrast, gastric fluid is usually grassy green, off-white to tan, or clear and colourless.
- A secondary method to confirm placement consists of marking the feeding tube with indelible ink at the exit site from the naris or lip at the time of radiography. You must confirm this mark before feeding or administering medication through the tube. Also record the measurement from naris to end of tube. The exit-point mark is not a foolproof indication of correct tube placement, inasmuch as the tube's distal tip can move from its original position while the external portion remains intact.
- **The auscultatory method should not be used to determine tube location.**
- The dye method (adding blue food colouring to enteral formula to assist with the detection of formula aspirated into the lung) is questioned because the absence of blue-stained tracheobronchial secretions does not rule out pulmonary aspiration. Health Canada (2003b) issued a public health advisory reporting an association between use of Blue No. 1 food colouring and patient deaths.

► BOX 42-15 Procedural Guideline

Obtaining Gastrointestinal Aspirate for pH Measurement, Large- and Small-Bore Feeding Tubes: Intermittent and Continuous Feeding

Critical Decision Point: Obtaining gastrointestinal aspirate for pH measurement to verify placement is crucial, whether a large- or small-bore tube is used and whether the tube will be used for decompression or feeding. *Note:* An X-ray examination to verify tube placement must be completed before enteral feedings are initiated.

Delegation Considerations:

The skill of measuring pH in gastrointestinal aspirate should *not* be delegated to unregulated care providers.

Equipment:

- 60 mL syringe
- pH test paper (scale of 0 to 11)
- Absorbent pad
- Small medication cup
- Disposable gloves

Procedure:

1. Perform hand hygiene. Perform measures to verify placement of tube:
 - A. For intermittently fed patients, test placement immediately before feeding (usually a period of at least four hours will have elapsed since previous feeding). More frequent checking has been associated with increased clogging of small-bore tubes. To avoid clogging, flush tube with 30 mL of water after aspirating for the residual volume (Bourgault et al., 2007).
 - B. For continuously tube-fed patients, check agency policy. If the patient is tolerating the feedings without incident and other indicators of correct location are present (the mark on the tube at the exit site has remained in its original position, and the most recent X-ray films confirm correct position of tube), it is reasonable to continue feedings. **If risk of tube displacement is high and the tube has moved, consider the need for an X-ray film to verify placement** (Metheny, 2006; Richardson et al., 2006). Plan to test pH at times when feeding may be withheld (e.g., during diagnostic testing, during chest physical therapy, or to avoid medication interaction).

Continued

► BOX 42-15 Procedural Guideline—cont'd

- C. Wait at least one hour after medication administration by tube or mouth.
2. Apply disposable gloves.
3. Draw 30 mL of air, or an equivalent amount for infants and children, into syringe, then attach syringe to end of feeding tube. Flush tube with the 30 mL of air to clear out formula or medications before attempting to aspirate fluid. It will probably be more difficult to aspirate fluid from the small intestine than from the stomach. Repositioning the patient from side to side may be helpful. More than one bolus of air through the tube may be needed in some cases.
4. Draw back on syringe and obtain 5 to 10 mL of gastric aspirate. Observe appearance of aspirate (see illustration Step 4A). Gently mix aspirate in syringe. Then expel a few drops into a clean medicine cup. Dip the pH strip into the fluid or apply a few drops of the fluid to the strip (see illustration Step 4B). Compare the colour of the strip with the colour on the chart provided by the manufacturer.
 - A. The pH of gastric fluid usually ranges from 1 to 4 (Bourgault et al., 2007).
 - B. The pH of intestinal fluid is usually higher than 6.

Step 4A Gastrointestinal contents. A, Stomach. B, Stomach. C, Intestinal. **Source:** Courtesy of Dr. Norma A. Metheny, Professor, St Louis University School of Nursing.

- C. Patients with continuous tube feeding may have a pH of 5 or higher.
- D. The pH of pleural fluid from the tracheobronchial tree is generally higher than 6.
5. Remove gloves and discard supplies. Perform hand hygiene.

Critical Decision Point: If after repeated attempts it is not possible to aspirate fluid from a tube that was originally confirmed by X-ray examination to be in the desired position, the tube is considered correctly placed if (1) no risk factors for tube dislocation exist, (2) the tube has remained in the original taped position and the tube's measurement remains constant, and (3) the patient is not experiencing difficulty (Metheny, 2006; Richardson et al., 2006). If in doubt, repeat radiographic examination of patient to confirm placement.

Major complications of enteral nutrition are outlined in Table 42-8. Of special note, severely malnourished patients are at risk for electrolyte disturbances from refeeding syndrome (metabolic disturbances that occur as a result of reinstituting nutrition) because cations such as potassium, magnesium, and phosphate move intracellularly during enteral nutrition or parenteral nutrition therapy.

Step 4B Comparing pH strip with colour chart.

BOX 42-16 NURSING STORY

Nourishing the Body, Nourishing the Soul: A Lesson in Enteral Nutrition and Life*

Jack was one of those patients who lingers in your mind and heart long after you are no longer providing care. I was a newly graduated nurse working on a busy medical unit, and Jack had been admitted several times for complications related to COPD (chronic obstructive pulmonary disease). Jack enjoyed interacting with the nurses and was quick to laugh. On one admission, Jack had suffered a stroke that affected his swallowing and mobility. His cognitive function remained intact and although his speech was a bit slurred, he was still able to communicate.

After weeks of enteral feedings, trials of oral intake, and swallowing assessments, it was decided that Jack would require long-term enteral feedings related to his swallowing dysfunction as the risk of aspiration pneumonia was too great to use oral feedings. Jack, unhappy with this assessment, was quieter than usual. He was a man who thoroughly enjoyed his food and found great pleasure in the daily rituals of eating and drinking. One evening as I connected his tube feedings, Jack looked at me and said, "You know, even people on death row get one last meal." I was relieved Jack was finally talking about this loss and found it fitting he chose humour to deal with it. When I asked Jack what his last meal would have been, he replied, "A big steak, mashed potatoes, and fiddleheads" (a green vegetable grown on riverbanks in the Maritime provinces).

From this experience, I became more appreciative of the taste and textures of the foods I ate, and the basic functions I had always taken for granted. Jack would often tease me about the food I had eaten, appalled that I had never eaten fiddleheads. When I told him I had finally tried them (yuck!) and that they must be an acquired taste, Jack's laugh was infectious!

Jack was discharged to a long-term care facility in his small town. A year later, he appeared again on my patient list, sadly, this time in palliative care. As I went to see him, I saw a man with dimmed physical strength but the same blue eyes. He could no longer communicate verbally, but his eyes showed that he remembered me. I cared for him for several days, talking about familiar subjects and sharing with him some of my jokes. This time, I felt I was nourishing his soul, versus nourishing his body.

Jack's children had rallied around him in the last days, and from them I was able to learn more about his life. One morning as they left the nursing unit to have breakfast and time to themselves, I assured them I would be with their father. I sat with Jack and rubbed his feet with lotion, while I gently talked to him. His laboured breathing eventually stopped and as I held his hand, he passed away. I was sad his family was not with him but also honoured to be present with him during his last moments.

As nurses, we can learn much about life from our patients. Jack taught me about nourishment ... of the mind, body, and soul, a lesson never to be forgotten.

*By Cheyanne Wyers, BN, RN.

► TABLE 42-8 Complications of Enteral Tube Feeding

Problem	Possible Cause	Intervention
Pulmonary aspiration	Regurgitation of formula Feeding tube displaced Patient in supine position	Verify tube placement Reposition tube and verify tube placement Elevate head of bed 30 to 45 degrees during feedings and for two hours afterward
	Deficient gag reflex	Reassess for return of normal gag reflex; until then, place patient on aspiration precautions and place patient in supine position
Diarrhea	Gastroesophageal reflux disease	Verify tube placement
	Delayed gastric emptying	Lower rate of delivery to increase tolerance
	Hyperosmolar formula or medications	Deliver formula continuously, deliver at lower rate, dilute formula, or change to isotonic enteral nutrition (physician order required and may consult with dietitian)
	Allergy to elixir ingredients (sorbitol)	Liquid medications are often sweetened with sorbitol; consider this as possible cause of diarrhea
	Antibiotic therapy	Antibiotics may destroy normal intestinal flora; physician may change medication; treat symptoms with antidiarrheal agents
Constipation	Bacterial contamination	Do not hang formula longer than 4–8 hours in bag; wash bag out well when refilling; change tube feeding bags q24h; use aseptic practices
	Malabsorption	Check expiration dates Check for pancreatic insufficiency; use low-fat, lactose-free formula and continuous feedings
	Lack of fibre	Select a formula containing fibre
	Lack of free water	Add water as needed as flushes*
	Medications	Evaluate side effects; suggest stool softener or bulk-forming laxative
Tube occlusion	Inactivity	Monitor patient's ability to ambulate; collaborate with physician for activity order or physiotherapy
	Pulverized medications given per tube	Irrigate with 30 mL water before and after each medication per tube*
	Insufficient tube irrigation	Ideally, each medication should be given separately
Tube displacement	Sedimentation of formula	Dilute crushed medications if not liquid
	Reaction of incompatible medications or formula	Shake cans well before administering (read label) Read pharmacological information on compatibility of drugs and formula
	Coughing, vomiting	Replace tube and confirm placement before restarting tube feeding
Abdominal cramping, nausea, or vomiting	Tube not taped securely	With placement verification, check that tape is secure (nasogastric)
	High osmolality of formula	Suggest an isotonic formula, or dilute current formula
		Suggest use of lactose-free formula
		Stop feeding if there is a risk of gastrointestinal tract obstruction
		Use greater proportion of carbohydrate
Delayed gastric emptying		Warm formula to room temperature
	Rapid increase in rate or volume	Lower rate of delivery to increase tolerance
	Delayed gastric emptying	If the gastric residual is >250 mL after a second gastric residual check, a promotility agent should be considered
		A full assessment should be conducted to find out reason for high level
		Suggest use of lactose-free formula
Serum electrolyte imbalance	Lactose intolerance	Stop feeding if there is a risk of gastrointestinal tract obstruction
	Intestinal obstruction	Use greater proportion of carbohydrate
	High-fat formula used	Warm formula to room temperature
	Cold formula used	Consult with physician regarding medication for increasing gastric motility
	Diabetic gastroparesis	Check for residual (see agency policy)
Increased respiratory quotient	Prematurity	Consult physician regarding advancing tube to intestinal placement
	Inactivity	Monitor medications and pathological conditions that may affect gastrointestinal motility
	Excess gastrointestinal losses	Monitor serum electrolyte levels daily
	Dehydration	Provide free water as per dietitian's recommendation
	Cirrhosis	Know of links with specific pathological condition
	Heart failure, edema	Monitor patient's weight
	Diabetes mellitus	Monitor glucose tolerance and type of feedings
	Overfeeding of carbohydrates	Balance kilocalorie needs provided from fat, protein, and carbohydrate with greater proportion of fat in formula (to decrease CO ₂ production)

Continued

► **TABLE 42-8** Complications of Enteral Tube Feeding—cont'd

Problem	Possible Cause	Intervention
Fluid overload	Refeeding syndrome in malnutrition Excess free water or diluted (hypotonic) formula	Restrict fluids if necessary, and use either a specialized formula or a diluted enteral formula at first Monitor levels of serum proteins and electrolytes Use a more concentrated formula with fluid volume excess that does not carry a risk of refeeding syndrome
Hyperosmolar dehydration	Hypertonic formula with insufficient free water	Slow rate of delivery, dilute, or change to isotonic formula

*Check first for fluid restrictions that would affect volume of water given. A physician's order is required to add free H₂O; this will be patient-specific.

► **BOX 42-17** Procedural Guideline**Providing Suction****Equipment:**

- Suction device, connecting tubing (connector as required)

Procedure:

1. Check the physician's order for type and amount of suction.
Suctioning may be ordered as continuous or intermittent.
The amount must be ordered by the physician.
2. To reduce patient's anxiety, educate patient about procedure.
3. Wash hands thoroughly to limit spread of microorganisms.
4. Set up suction device as per institution or agency policy.
5. Set type and amount of suction as ordered.

6. Monitor patient and suction system regularly. Provide data for overall care. Monitor for bleeding or blockage:

Patient: Note abdominal distension, nausea, feeling of discomfort, bowel sounds, electrolyte levels.

Device: Note kinks, blockages, flow, and settings.

Drainage: Note amount, colour, and consistency.

7. Secure tubing as described in preceding enteral nutrition section. Keep tubing higher than stomach to facilitate drainage. Secure tubing to prevent inadvertent pulling or removal.
8. Measure output at least every eight hours or as per institutional or agency policy.
9. Document as per institution or agency protocol.

► **SKILL 42-6** Inserting a Large-Bore Nasoenteric or Orogastric Tube for Gastric Suctioning**Delegation Considerations**

This skill requires problem solving and knowledge application unique to a professional nurse. For this reason, this skill should *not* be delegated to unregulated care providers.

Equipment

- Nasogastric or nasointestinal (orogastric or orointestinal) tube (12- to 18-Fr)
- Stethoscope
- 60 mL or larger Luer-Lok or catheter-tip syringe
- Hypoallergenic tape and tincture of benzoin or tube fixation device
- Scissors
- pH indicator strip (scale of 0 to 14)
- Glass of water and straw (not required for intubated patients)
- Water-soluble lubricant
- Emesis basin
- Absorbent pad
- Facial tissues
- Disposable gloves (multiple pairs needed)
- Suction equipment in case of aspiration
- Penlight to check placement of nasopharynx
- Tongue blade
- Disposable tape measure
- Felt-tip marker
- Suction device for continuous or intermittent suctioning

Procedure**STEPS**

1. Assess patient for the need for large-bore tube (i.e., for gastric suctioning or lavage).
 - A. Review physician's order for type of tube and enteral feeding schedule.

RATIONALE

- Identify patients who require gastric drainage or flushing.
- **Procedure and tube feedings require a physician's order.**

► SKILL 42-6 Inserting a Large-Bore Nasoenteric or Orogastric Tube for Gastric Suctioning—cont'd

2. Perform hand hygiene. Assess patency of nares. Have patient close each nostril alternately and breathe. Examine each naris for patency and skin breakdown.
 3. Assess the gag reflex. Place tongue blade in patient's mouth, touching uvula to induce a gag response.
- Nares may be obstructed or irritated, or septal defect may be present.
 - Assessing gag reflex identifies patient's ability to swallow and determines whether a risk for aspiration exists.

Critical Decision Point: Patients with impaired level of consciousness or who are intubated and sedated may also have impaired gag reflex, and their risk of aspiration is increased during this type of procedure and subsequent tube feedings. For a patient who is intubated, sedated, or too ill to participate, ensure that the patient's head is tilted toward the chest for enteral feeding tube insertion.

4. Review patient's medical history for nasal problems (e.g., nosebleeds, oral or facial surgery, anticoagulation therapy, history of aspiration).
 5. Auscultate patient's abdomen for bowel sounds.
 6. Perform hand hygiene (before auscultating abdomen).
 7. Explain procedure to patient and how to communicate during intubation by raising index finger to indicate gagging or discomfort.
 8. Stand on same side of bed as naris for insertion, and assist patient to high Fowler's position unless that position is contraindicated. Place pillow behind patient's head and shoulders.
 9. Place absorbent pad over patient's chest. Keep facial tissues within reach.
 10. Determine length of tube to be inserted, and mark with tape. Traditional method: Measure distance from tip of nose to earlobe to xiphoid process of sternum (see Step 10 illustration).
- Nasoenteral tubes are contraindicated in patients who have undergone recent nasal surgery, have sustained facial traumas, have nosebleeds, or are receiving anticoagulation therapy. Because of risk for improper tube placement, tubes are also contraindicated in patients who have undergone surgical procedures in which a transsphenoid approach was used to remove pituitary tumours (Metheny, 2002).
 - Absence of bowel sounds may indicate decrease in or absence of peristalsis and increased risk for aspiration or abdominal distension.
 - Hygiene reduces transfer of microorganisms.
 - Information reduces anxiety and helps patient assist in insertion. Patients who are alert and communicating tolerate the procedure better than other patients.
 - Fowler's position allows easier manipulation of tube, reduces risk of aspiration, and promotes effective swallowing.
 - Pad prevents soiling of gown. Insertion of tube may cause patient's eyes to tear.
 - Length approximates distance from nose to stomach in 98% of patients. For duodenal or jejunal placement, an additional 20 to 30 cm is required.

Step 10 Length of tube to be inserted is equal to distance from tip of nose to earlobe to xiphoid process.

11. Prepare nasogastric or nasointestinal tube for intubation.
 12. Perform hand hygiene, and put on gloves.
 13. Cut tape 10 cm long or prepare tube fixation device. Split one end of tape lengthwise 5 cm.
 14. Dip tube with surface lubricant into glass of water. If tube is not self-lubricating, then water-soluble lubricant should be used.
 15. Insert tube through nostril to back of throat (posterior nasopharynx). Aim back and down toward ear.
 16. Have patient tilt head toward chest after tube has passed through nasopharynx.
- Hygiene and gloves reduce transmission of microorganisms.
 - To be used to anchor tubing after insertion.
 - Activates lubricant to facilitate passage of tube into nares to gastrointestinal tract. Do not use petroleum-based products due to the risk of aspiration into the lung and a resultant chemical pneumonitis.
 - Natural contour facilitates passage of tube into gastrointestinal tract and reduces gagging by patient.
 - Tilting head forward closes off glottis and reduces risk of tube's entering trachea. This technique is also used in patients who are intubated and sedated.

Critical Decision Point: Encourage patients who are alert and communicating to swallow by giving small sips of water or ice chips when possible. For patients who are intubated and sedated or not able to participate, tilt head toward chest. Advance the tube as patient swallows or as head is tilted toward chest. Rotate tube 180 degrees while inserting.

> SKILL 42-6 Inserting a Large-Bore Nasoenteric or Orogastric Tube for Gastric Suctioning—cont'd

17. Emphasize the need to mouth-breathe and swallow during the procedure (when possible).
 18. When tip of tube reaches the carina (about 25 cm in an adult), stop insertion, hold end of tube near your ear, and listen for air exchange from the distal portion of the tube.
- Mouth-breathing and swallowing facilitate passage of tube and alleviate patient's fears during the procedure.
 - **If air is heard, the tube could be in the respiratory tract; remove tube and start over. This listening step should never be used to verify tube placement** (Metheny, 2006).

Critical Decision Point: Do not force tube insertion. If resistance is met or patient starts to cough, choke, or become cyanotic, stop advancing the tube and pull tube back.

19. Check for position of tube in back of throat with penlight and tongue blade.
 20. Perform measures to verify placement of tube, by measuring pH.
 - A. Examine gastric contents and yield.
- Tube may be coiled, kinked, or entering trachea. (Withdraw tube immediately if tube is coiled, if respiratory status of patient changes, or if patient begins to cough and skin colour changes; if distress is not present, withdraw tube fully and retry. Note whether tube was kinked; if so, it is likely to kink again in the same place.)
 - Note: Tube placement must be verified by X-ray examination before enteral feeds are initiated. Another test that can be done at the bedside to ensure ongoing placement is to measure pH of aspirated gastric fluids.
 - Respiratory and gastric contents may look similar, but aspirating gastric contents yields a greater amount, whereas aspirating respiratory contents may yield only a few millilitres.

Critical Decision Point: Auscultation is no longer considered a reliable method for verification of tube placement because a tube inadvertently placed in the lungs, pharynx, or esophagus can transmit a sound similar to that of air entering the stomach (Metheny, 2006; Richardson et al., 2006; Wagner, 2004).

21. After gastric aspirates are obtained, anchor tube to patient's nose and avoid pressure on nares. Mark exit site on tube with indelible ink. Select one of the following options to secure tube:
 - A. Apply tape
 - (1) Apply tincture of benzoin or other skin adhesive on tip of patient's nose and tube and allow it to become "tacky."
 - (2) Place intact end of tape over bridge of patient's nose. Wrap each of the 5 cm strips around tube as it exits nose.
 - B. Apply tube fixation device, using shaped adhesive patch.
 - (1) Apply wide end of patch to bridge of patient's nose.
 22. Fasten end of nasogastric tube to patient's gown with a piece of tape (not safety pin).
 23. Remove gloves. Perform hand hygiene and apply clean gloves, and administer oral hygiene (see Chapter 37). Cleanse tubing at nostril.
 24. Remove gloves, dispose of equipment, and perform hand hygiene.
 25. Inspect nares and oropharynx for any irritation after insertion.
 26. Ask patient whether he or she feels comfortable.
 27. Observe patient for any difficulty breathing, for coughing, or for gagging.
 28. Auscultate lung sounds.
 29. Connect tube to suction device as ordered.
- A properly secured tube allows the patient more mobility and prevents trauma to nasal mucosa. Mark tube at tip of nares; measure from line to end of tube; tape and secure to maintain position.
 - Skin adhesive helps tape adhere better and protects skin.
 - Securing tape to nares prevents tissue necrosis.
 - Device secures tube and reduces friction on nares.
 - Fastening tape to gown reduces traction on the nares if tube moves. Tape is recommended because safety pins may become unfastened and possibly cause injury to the patient.
 - Oral hygiene promotes patient comfort and integrity of oral mucous membranes.
 - Hygiene reduces transmission of microorganisms.
 - If tube insertion was difficult, irritation of nares or oropharynx may have occurred.
 - Patients' level of comfort is evaluated. (This may be a challenge if a language barrier exists or if the patient has dementia or is confused.)
 - Improper position of the tube may cause these symptoms or increase symptoms in patients who have heart failure, pneumonia, asthma, and other cardiac or respiratory conditions.
 - Abnormal lung sounds can be an early sign of aspiration.
 - May be ordered as a continuous or intermittent suction and at various pressures (e.g., 80 mm Hg). In some circumstances, tubes are placed by surgeon but contraindicated or strict protocols for flush or suction (i.e., post esophagectomy).

Medication

It is recommended that medications *not* be administered via large-bore tube while suctioning is required. If a large-bore tube must be used, then suctioning should be withheld for at least 30 minutes after medication is administered. Consult with pharmacist and refer to institutional or agency policy.

Parenteral Nutrition

Parenteral nutrition is a form of specialized nutrition support in which nutrients are provided intravenously. Safe administration of this form of nutrition depends on appropriate assessment of nutrition needs, meticulous management of the central venous catheter (CVC) or central venous access device (CVAD), and careful monitoring to prevent or treat metabolic complications. Parenteral nutrition is administered in a variety of settings, including the patient's home. Regardless of the setting, the nurse adheres to the same principles of asepsis and infusion management to ensure safe nutrition support.

Patients who are unable to digest or absorb enteral nutrition benefit from parenteral nutrition. Patients in highly stressed physiological states, such as sepsis, head injury, or burns, are also candidates for parenteral nutrition therapy. Box 42-18 lists other indications for parenteral nutrition. Clinical and laboratory monitoring by a multidisciplinary team is required throughout parenteral nutrition therapy. The need for continued parenteral nutrition is re-evaluated regularly, with the goal of eventually using the gastrointestinal tract. Disuse of the gastrointestinal tract has been associated with villus atrophy and generalized cell shrinkage. Translocation of bacteria from the local gut to systemic regions has been noted in relation to gastrointestinal cell shrinkage; such translocation can result in gram-negative septicemia.

Lipid emulsions provide supplemental kilocalories and prevent deficiencies of essential fatty acids. These emulsions can be administered through a separate peripheral catheter, through the CVC by Y-connector tubing (see Chapter 39), or

as an admixture to the parenteral nutrition solution. The addition of lipid emulsion to the parenteral nutrition solution is called a *3-in-1 admixture* and is administered over a 24-hour period. The admixture should not be used if oil droplets are observed or if an oil or creamy layer is observed on the surface of the admixture. This observation indicates that the emulsion has broken into large lipid droplets that can cause fat emboli if administered. Lipid emulsions are white and opaque; thus, care should be taken to avoid confusing enteral formula with parenteral lipids.

Contraindications to giving lipids are hyperlipidemia, lipid nephrosis, severe liver failure, and egg allergy (patient should be asked about egg allergy during history taking).

Initiating Parenteral Nutrition

Patients with short-term nutritional needs often receive intravenous solutions of less than 10% dextrose in a peripheral vein in combination with amino acids and lipids. Peripheral solutions are not as calorically dense and therefore are less irritating to the peripheral veins, and their use is usually temporary. Administering parenteral nutrition with greater than 10% dextrose requires a CVC (Figure 42-12) that is placed into a high-flow central vein (such as the superior vena cava) by a physician using sterile technique (see Chapter 39).

Nurses who have special training insert peripherally inserted central catheters (PICCs) that are started in a vein of the forearm or upper arm and threaded into the subclavian vein or the superior vena cava (Figure 42-13).

After central catheter or PICC placement is verified by chest X-ray examination or radiographically confirmed and documented, the catheter is flushed with saline or heparin. The physician may suture the CV catheter in place. A PICC is usually stabilized with sterile strips of tape and a sterile dressing. The types of dressings to be applied vary between institutions and a variety of policies and protocols are adhered to. The nurse who is new to the nursing unit can check the appropriate dressing protocol and policy before proceeding. Wing-to-tip of the PICC should be measured and documented daily. With a tube suspected to be migrating 2 cm or more, all fluids should be stopped and radiography should be repeated for

► BOX 42-18

Indications for Parenteral Nutrition

Nonfunctional Gastrointestinal Tract

- Massive small bowel resection or gastrointestinal surgery
- Paralytic ileus
- Intestinal obstruction
- Trauma to abdomen, head, or neck
- Severe malabsorption
- Intolerance of enteral feeding (established by trial)
- Chemotherapy, radiation therapy, bone marrow transplantation

Extended Bowel Rest

- Enterocutaneous fistula
- Inflammatory bowel disease exacerbation
- Severe diarrhea
- Moderate to severe pancreatitis

Preoperative Total Parenteral Nutrition

- Preoperative bowel rest
- Treatment for comorbid severe malnutrition in patients with nonfunctional gastrointestinal tracts
- Severely catabolic patients when gastrointestinal tract is nonusable for more than four to seven days

Figure 42-12 Parenteral Nutrition via CVC. **Source:** Mosby's dictionary of medicine, nursing, and health professionals (8th edition), 2009. St Louis, MO: Mosby.

Figure 42-13 PICC line insertion.

placement verification. Also to verify placement, the PICC line may be flushed by specially trained nurses and if noted to be occluded, special procedures (e.g., alteplase) are carried out to ensure line patency.

Before beginning any parenteral infusion, the nurse verifies the physician's order and inspects the solution for particulate matter or a break in the lipid emulsion. An infusion pump is always used. An initial rate of 40 to 60 mL/hour may be recommended. In some institutions, the solutions are infused separately at a specified rate until the therapy is no longer required. In this instance, each solution would have a separate infusion pump. Parenteral nutrition in the hospital is infused 24 hours a day. The parenteral infusion is refrigerated until needed, while the lipids are stored at room temperature.

The rate is gradually increased until the patient's complete nutrition needs are supplied. Patients who receive parenteral nutrition at home frequently administer the entire daily solution over 12 hours at night. This allows the patient to disconnect from the infusion each morning, flush the central catheter, and have independent mobility during the day.

Preventing Complications

Complications of parenteral nutrition include mechanical complications from insertion of the CVC, infection, and metabolic alterations (Table 42-9). Pneumothorax occurs when a puncture in the pulmonary system results in accumulation of air in the pleural cavity and subsequent impairment in breathing. Pneumothorax is usually accompanied by symptoms of sudden sharp chest pain, dyspnea, and coughing. In relation to parenteral nutrition, pneumothorax most often occurs during CVC placement.

Air embolus can occur during insertion of the catheter or when the tubing or cap is changed. Having the patient perform a Valsalva manoeuvre (holding his or her breath and "bearing down") while assuming a left lateral decubitus position can prevent air embolus. The increased venous pressure created by the manoeuvre prevents air from entering the bloodstream during catheter insertion.

To avoid infection, the infusion tubing should be changed regularly. A filtered tubing is required, and most institutions require the tubing be changed every 24 hours. During central catheter dressing changes, sterile mask and gloves are always used, and insertion sites assessed for signs and symptoms of infection (see Chapter 32).

Electrolyte abnormalities should be corrected before starting parenteral nutrition. Calorie goals should be reached gradually. It is very important to base the caloric and protein needs on the patient's current weight to avoid overfeeding. The parenteral nutrition solution contains most of the major electrolytes, vitamins, and minerals. Potassium, magnesium, and phosphorous levels should be closely monitored, as well as intake and output during the first week of parenteral therapy. Supplemental vitamin K must be given as ordered throughout therapy. Vitamin K can be synthesized by microflora found in the jejunum and ileum with normal use of the gastrointestinal tract; however, because parenteral nutrition circumvents gastrointestinal use, exogenous vitamin K must be administered.

Electrolyte and mineral imbalances may occur. Ingestion of concentrated glucose is accompanied by increases in endogenous insulin production, which causes cations (potassium, magnesium, and phosphorus) to move intracellularly. In malnourished or cachectic patients, the resulting low serum (extracellular) levels of electrolytes and edema may cause cardiac dysrhythmias, heart failure, respiratory distress, convulsions, coma, or death. This has been called *refeeding syndrome*.

Too-rapid administration of hypertonic dextrose can result in an osmotic diuresis and dehydration (see Chapter 39). Thus, if an infusion falls behind schedule, the nurse should not increase the rate in an attempt to catch up. Sudden discontinuation of the solution can cause hypoglycemia. Usually, 10% dextrose is infused when parenteral nutrition solution is suddenly discontinued. Patients with diabetes are especially at risk for this development.

Repeated or traumatic catheter insertions place patients at risk for central vein thrombosis. Prevention of catheter-related thromboses includes proper positioning of the catheter and prevention of infections. Although flushes with thrombolytic agents such as heparin might prevent catheter-related thromboses, confirmatory research and cost-effectiveness analysis of this approach are needed before it is recommended (Baskin et al., 2009).

The goal is for patients to switch from parenteral nutrition to enteral nutrition or oral feeding, or both. Specified weights and intakes are recorded. Once patients are meeting one-third to one-half of their kilocalorie needs per day, parenteral nutrition is usually decreased to half the original volume. Enteral nutrition feedings should then be increased to meet needs. When 75% of daily energy needs are consistently met with

► TABLE 42-9 Complications of Parenteral Nutrition (PN)

Problem	Signs and Symptoms	Intervention
Air embolism	Tachypnea, apnea, wheezing, hypotension, cyanosis	Turn patient to left lateral decubitus position, instruct patient to perform Valsalva manoeuvre, and lower head of bed. Cap the open end of catheter or tape perforation in catheter wall. Administer oxygen; notify physician. Maintain integrity of closed system to prevent air emboli, and have patient perform Valsalva manoeuvre when cap is changed.
Catheter occlusion	No flow or sluggish flow through the catheter	Temporarily stop infusion and flush with saline or heparin. If effort to flush is unsuccessful, attempt to aspirate clot; if still unsuccessful, follow protocol for use of thrombolytic agent (e.g., alteplase). Alteplase has been shown to be effective in restoring catheter patency.
Catheter sepsis	Fever, chills, glucose intolerance, positive blood culture	To prevent, change catheter site dressing if it becomes wet or contaminated, use aseptic technique when changing dressing or when handling IV tubing, catheter caps, or parenteral nutrition containers. Do not hang a single container of parenteral nutrition for more than 24 hours or a container of lipids more than 12 hours; use an inline 0.22 mcg filter to remove bacteria.*
Electrolyte imbalance	Monitor Na, Ca, K, Cl, PO ₄ , Mg, and CO ₂ levels	See Chapter 39 for signs of deficiency or toxicity. Check total parenteral nutrition (TPN) for supplemental electrolyte levels at regular intervals—often weekly. Notify physician of imbalances.
Hypercapnia	Increased oxygen consumption, increased CO ₂ , respiratory quotient >1.0, minute ventilation	Ventilator-dependent patients are at risk; to prevent, monitor parameters, provide 30% to 60% of energy requirements as fat per physician's order.
Hypoglycemia	Diaphoresis, shakiness, confusion, loss of consciousness	To prevent, do not discontinue PN abruptly but taper rate down to within 10% of infusion rate one to two hours before stopping. If hypoglycemia is suspected, test blood glucose level, and administer IV bolus of dextrose per physician order if necessary.
Hyperglycemia	Thirst, headache, lethargy, increased urination	Monitor blood glucose level daily until it is stable and then as ordered or as needed. PN is initiated slowly and tapered up to maximal infusion rate. Additional insulin may be required during therapy if problem persists (or if patient has diabetes mellitus).
Hyperglycemic hyperosmolar nonketonic dehydration or coma	Hyperglycemia (>500 mg/dL), glycosuria, serum osmolality >350 mOsm/L, confusion, azotemia, headache, severe signs of dehydration (see Chapter 39), hypernatremia, metabolic acidosis, convulsions, coma	To prevent, monitor blood glucose, blood urea nitrogen, serum osmolality, glucose in urine, and fluid losses; administer insulin as ordered; replace fluids as needed; maintain consistent infusion rate; and provide 30% of daily energy needs as fat. Patients at risk are those who are hypermetabolic, those receiving steroids, older adults, diabetic patients, those who have impaired renal or pancreatic function, and those who are septic.
Pneumothorax	Severe dyspnea, cyanosis, radiographic confirmation	Complication that occurs upon catheter insertion may evolve slowly afterward. Monitor patient for first 24 hours for pulmonary distress.
Thrombosis of central vein	Unilateral edema of neck, shoulder, and arm; pain	Notify physician.

*With 3-in-1 admixture TPN, filtration is not possible because of large lipid molecules.

tube feeding, parenteral nutrition may be discontinued. Patients who make the transition from parenteral nutrition to oral feedings typically have early satiety and decreased appetite. Calorie and protein counts are recommended when patients begin taking soft foods. Parenteral nutrition should be gradually decreased in response to increased oral intake. If oral intake is inadequate, small, frequent meals may prove helpful. When 75% of needs are being met by reliable dietary intake or intake analysis, parenteral nutrition therapy may be discontinued. Some institutions will discontinue lipid emulsion first, then parenteral infusion is continued until requirements are met.

✦ KEY CONCEPTS

- Nurses must have current, culturally sensitive nutritional knowledge to apply to the complexities of health care and illness and to the changing needs of diverse populations and demographics.
- A balanced diet featuring carbohydrates, fats, proteins, vitamins, and minerals provides the essential nutrients to carry out the body's normal physiological functioning throughout the lifespan.
- Through digestion, food is broken down into its simplest form for absorption. Digestion and absorption occur mainly in the small intestine.

- Dietary reference intakes (DRIs) provide a range of values that address the needs of groups (estimated average requirement) and individuals (adequate intakes, recommended dietary allowances, and tolerable upper intake level).
 - Guidelines for dietary change advocate reduced saturated and trans fat, reduced sodium, and reduced refined sugars, as well as an increased intake of complex carbohydrates and fibre.
 - Nutritional screening helps to identify patients at risk of malnourishment. Because improper nutrition can affect all body systems, nutritional assessment includes total physical assessment.
 - Interdisciplinary collaboration is essential to helping a patient achieve optimal nutrition.
 - Special diets alter the composition, texture, digestibility, and residue of foods to suit the patient's particular needs.
2. Essential nutrients
 1. Are made by the body
 2. Generally must be supplied by food
 3. Include alcohol
 4. Are enzymes
 3. Positive nitrogen balance would occur in
 1. Infection
 2. Starvation
 3. Burn injury
 4. Pregnancy
 4. The major determinant of healthy eating is
 1. Educational level
 2. Income
 3. Food preferences
 4. Vitamin supplementation

✦ CRITICAL THINKING EXERCISES

1. Charlene MacDonald, a 63-year-old accountant, is overweight with a sedentary lifestyle, uses alcohol infrequently, consumes restaurant food for most meals, and takes 400 IU of vitamin D daily. She wants to undergo cataract surgery to improve her vision; however, the surgeon has advised her to take off at least 10 kg of weight before the operation. Ms. MacDonald weighs 90 kg and has a height of 156 cm. Her waist circumference is 100 cm. What indications would lead you to believe Ms. MacDonald is adequately caring for her health? What additional laboratory tests and dietary and health history information are needed to perform a comprehensive nutritional assessment? What conclusions can you draw from the information available about Ms. MacDonald's weight status? Using *Eating Well With Canada's Food Guide*, what suggestions would you make to Ms. MacDonald to help her achieve weight loss?
2. Corey Green, a 32-year-old mother, is considering switching her entire family to a vegan diet because she believes it will make her 3-year-old twin daughters healthier. What nutritional concerns should you watch for? How would you assess the family's nutritional needs and monitor for such concerns? What advice would you offer to Corey to enhance her family's health while following a vegan diet? Plan one day of meals for this family, indicating food servings for the twins that would meet their protein needs and respect the vegan food diet.
3. Daniele, a middle-school student, is unhappy with her shape and weight. Using an Internet site, she calculated her BMI as 29 one month ago. "I am the smallest person in my family, but I am too fat!" she thought. During the past four months, she has skipped breakfast and lunch and exercised for two hours a day to "tone up." Her skin, lips, and hair are becoming dry. Daniele denies having lost weight even though her clothes look loose and baggy. Her friends told the homeroom teacher that Daniele goes to the bathroom immediately after eating any food. The teacher requests that you plan a session with Daniele to increase her understanding of her daily nutritional requirements and of healthy eating patterns. What will you discuss with Daniele?
4. Older adults at risk for malnutrition
 1. Have the security of living on a fixed income
 2. Know about the amounts of fat, sodium, and cholesterol in the foods they eat
 3. Experience age-related gastrointestinal changes such as reduced saliva production, increased taste threshold, and decreased peristalsis
 4. Have diseases such as diabetes and depression well controlled
5. When a patient is unable to take fluid or food by eating normally over an extended period of time, which of the following is the best alternative?
 1. Liquid nutrients through a tube leading from the nose to the stomach or intestine
 2. Giving solutions through a tubing in a peripheral vein
 3. Giving continuous tube feedings regulated via an electric feeding pump
 4. Giving feedings through a tube inserted through the skin and tissue of the abdomen
6. A nutrient content claim of *light* means
 1. The food may be light in colour
 2. The food has no added sugar or salt
 3. The food is reduced in calories or fat by 10%
 4. The levels of saturated and trans fatty acids are restricted
7. When a mother tells you that she would like to switch her 15-month-old toddler from whole to skim milk so the child will not get "too fat," you encourage her to continue with the whole milk because
 1. Whole milk has more calcium than skim
 2. Whole milk has a longer refrigerated storage life
 3. Whole milk costs the same as skim milk
 4. Whole milk contains fatty acids needed for the toddler's brain development
8. Which of the following interventions is appropriate for the patient experiencing dysphagia?
 1. Encourage the patient to rest lying down for at least 30 minutes after a meal
 2. Offer thin liquids to make swallowing easier
 3. Place the food on the strong side of the patient's mouth
 4. Leave the patient with all food items within easy reach and tell the patient when you will come back to take away the tray

✦ REVIEW QUESTIONS

1. A function of carbohydrates in the diet is to
 1. Enable chemical reactions
 2. Promote growth and repair of tissues
 3. Supply energy
 4. Maintain water balance

10. The nursing activity *most* likely to prevent the clogging of a nasogastric feeding tube is
 1. Attaching the tubing to suction after each feeding
 2. Filling the tube with water and clamping it after each feeding
 3. Clamping the tube before all of the nourishment has drained
 4. Giving the patient ice chips to suck after each feeding

Urinary Elimination

Original chapter by Terry L. Wood, RN, CNE, PhD

Canadian content written by Kathleen F. Hunter, RN, NP, PhD, GNC(C), NCA

objectives

Mastery of content in this chapter will enable you to:

- Define the key terms listed.
- Describe the process of urination.
- Identify factors that commonly influence urinary elimination.
- Compare common alterations in urinary elimination.
- Identify two modalities of renal replacement therapy.
- Obtain a nursing health history for a patient with urinary elimination problems.
- Identify nursing diagnoses appropriate for patients with alterations in urinary elimination.
- Obtain urine specimens.
- Describe characteristics of normal and abnormal urine.
- Describe the nursing implications of common diagnostic tests of the urinary system.
- Discuss nursing measures to promote normal micturition and to reduce episodes of incontinence.
- Insert a urinary catheter.
- Discuss nursing measures to reduce urinary tract infection.
- Irrigate a urinary catheter.

Normal elimination of urinary wastes is a basic function that most people take for granted. When the urinary system fails to function properly, virtually all organ systems will be affected eventually. Patients with alterations in urinary elimination also may suffer emotionally from changes in body image. It is important that you be understanding and sensitive to all of your patients' needs. Understanding the reasons for urinary elimination problems and finding acceptable solutions are essential nursing functions.

Scientific Knowledge Base

Urinary elimination depends on the functioning of the kidneys, ureters, bladder, and urethra. Kidneys remove wastes from the blood to form urine. Ureters transport urine from the kidneys to the bladder. The bladder stores urine until the urge to urinate develops. Urine then leaves the body through the urethra. All organs of the urinary system must be intact and functional for successful removal of urinary waste (Figure 43-1).

Upper Urinary Tract

Kidneys. The kidneys lie on either side of the vertebral column behind the peritoneum and against deep muscles of the back. The kidneys extend from the twelfth thoracic vertebra to the third lumbar vertebra. Normally, the left kidney is higher than the right one because of the anatomical position of the liver.

Waste products of metabolism that collect in the blood are filtered in the kidneys. Blood reaches each kidney by a renal (kidney) artery that branches from the abdominal aorta. Approximately 20% to 25% of the cardiac output circulates each minute through the kidneys. The nephron, the functional unit of the kidney, forms the urine. The **nephron** is composed of the glomerulus, Bowman's capsule, proximal convoluted tubule, loop of Henle, distal tubule, and collecting duct (Figure 43-2). Each kidney contains approximately 1 million nephrons (Sherwood, 2007).

A cluster of blood vessels forms the capillary network of the glomerulus, which is the initial site of filtration of the blood

and the beginning of urine formation. The glomerular capillaries permit filtration of water, glucose, amino acids, urea, creatinine, and major electrolytes into Bowman's capsule. Large proteins and blood cells normally do not filter through the glomerulus. The presence of large proteins in urine (**proteinuria**) is a sign of glomerular injury.

The glomerulus filters approximately 125 millilitres of plasma per minute (180 litres per day). Most (99%) of the filtrate is reabsorbed into the plasma, with the remaining 1% excreted as urine (Sherwood, 2007). The kidneys play a key role in fluid and electrolyte balance (see Chapter 39). Although output does depend on intake, normal adult urine output is 1500 to 1600 mL/day. An output of less than 30 mL/hour may indicate renal alterations.

The kidneys produce several substances vital to the production of red blood cells (RBCs), blood pressure regulation, and bone mineralization. The kidneys are responsible for maintaining a normal RBC volume by producing **erythropoietin**, a hormone that functions within the bone marrow to stimulate RBC production and maturation and that prolongs the life of mature RBCs (Sherwood, 2007). Patients with chronic alterations in kidney function cannot produce sufficient quantities of this hormone and are therefore prone to anemia.

Renin is another hormone produced by the kidneys. Its major role is the regulation of blood flow in times of renal ischemia (decreased blood supply). Renin is released from the juxtaglomerular cells (Figure 43-3) and functions as an enzyme to convert angiotensinogen (a substance synthesized by the liver) into angiotensin I. Angiotensin I is converted to angiotensin II in the lungs. Angiotensin II causes vasoconstriction and stimulates aldosterone release from the adrenal cortex. Aldosterone causes retention of water, which increases blood

volume. Both of these mechanisms increase arterial blood pressure and renal blood flow (Sherwood, 2007). The kidneys also produce prostaglandin E2 and prostacyclin, which are important in maintaining renal blood flow through vasodilation.

The kidneys play a role in calcium and phosphate regulation by producing a substance that converts vitamin D into its active form. Patients with chronic alterations in kidney function do not make sufficient amounts of active vitamin D. They are prone to develop renal bone disease resulting from the demineralization of bone caused by impaired calcium absorption.

Ureters. Urine enters the **renal pelvis** from the collecting ducts and travels to the bladder through the ureters. The ureters are tubular structures that enter the urinary bladder obliquely through the posterior wall, at the ureterovesical junction (the juncture of the ureters and the bladder). This arrangement normally results in compression of the ureter at the junction during **micturition** (urination) to prevent the reflux of urine.

Peristaltic waves cause urine to enter the bladder in spurts rather than steadily. An obstruction within a ureter, such as a kidney stone (**renal calculus**), results in strong peristaltic waves that attempt to move the obstruction into the bladder. These strong peristaltic waves often result in pain known as **renal colic**.

Lower Urinary Tract

Bladder. The urinary bladder is a hollow, distensible muscular organ that stores and excretes urine. When empty, the bladder lies behind the symphysis pubis in the pelvic cavity. It rests against the anterior wall of the rectum in men and against the anterior walls of the cervix and vagina in women (Figure 43-4).

The bladder expands as it becomes filled with urine. Pressure increases only minimally during bladder filling because the relaxed bladder is normally highly compliant (Fry et al., 2005). When the bladder is full, it expands and extends above the symphysis pubis. A very distended bladder may reach the umbilicus. In a pregnant woman, the developing fetus pushes against the bladder, reducing its capacity and causing a feeling of fullness. This effect is more likely to occur in the first and third trimesters.

The main muscle of the bladder is the **detrusor muscle**. Contraction of the detrusor expels urine from the body. The **trigone** is a triangular area of smooth muscle at the base of the bladder. An opening exists at each of the trigone's three angles, two for the ureters and one for the urethra.

Urethra. Urine travels from the bladder through the urethra (a fibromuscular tube) and passes outside of the body through the **urethral meatus**. In women, the urethra is approximately 4 cm long. This short length predisposes women and girls to infection. The male urethra is about 20 cm long and serves as both a urinary canal and a passageway for cells and secretions from reproductive organs. The male urethra has three sections: the prostatic urethra, the membranous urethra, and the penile urethra. The prostatic urethra pierces the anterior portion of the **prostate gland** (see Figure 43-4, A).

The ability of the urethra to maintain adequate closure pressure between voids is critical to retaining urine in the bladder (Ashton-Miller & DeLancey, 2007), particularly because intra-abdominal pressure increases during coughing, lifting, laughing, and sneezing. This task is accomplished through a combination of factors known collectively as the **urethral closure mechanism**. Detrusor muscle surrounds the urethra at the level of the **bladder neck**, helping to constrict the opening. Circular smooth muscle as well as striated sphincter muscle (also known as the external sphincter, or **rhabdosphincter**) comprise the proximal two-thirds of the urethra and play an important role in sustaining tone. In addition, a highly vascular mucosal surface helps to maintain a watertight seal (Ashton-Miller & DeLancey, 2007). The striated musculature of the pelvic floor surrounds the urethra and provides additional closure pressure. Finally, increases in intra-abdominal pressure, such as those that occur during coughing and sneezing, are normally transmitted to the bladder neck, enhancing closure of the proximal urethra during stress (Griffiths et al., 2005).

Act of Urination

The act of urination relies on the coordinated effort of the bladder and the urethral closure mechanism. The adult bladder normally holds approximately 500 mL of urine and empties, on average, five to seven times per day. As the bladder becomes distended and as it is deemed appropriate to urinate, the detrusor (bladder muscle) contracts and the urethral sphincter mechanism relaxes to allow expulsion of urine (Morrison et al., 2005).

Several brain structures influence urination. As the bladder fills, sensory impulses are sent to the sacral spinal cord and relayed to the **pontine micturition centre**. If a person is ready to void, the pontine micturition centre relays the impulses back to initiate detrusor contraction, sphincter relaxation, and bladder emptying. If a person chooses not to void, the impulses are relayed to the cerebral cortex for voluntary inhibition of a detrusor contraction. If the urge to void has been ignored repeatedly, bladder capacity may be reached and the resulting pressure on the sphincter may make continued voluntary control impossible (Morrison et al., 2005).

Factors Influencing Urination

Many factors influence the volume and quality of urine and the patient's ability to urinate. Some pathophysiological conditions may be acute and reversible (urinary tract infection), whereas others may be chronic and irreversible (slow, progressive development of renal dysfunction).

Disease Conditions. The complex role that the nervous system plays in urinary elimination suggests that any disruption to the central or peripheral pathways can affect urination. Between 40% and 60% of individuals admitted to hospital after a cerebrovascular accident experience urinary incontinence, and 15% remain incontinent one year later (Thomas et al., 2008). Between 30% and 50% of patients with multiple sclerosis experience urgency, frequency, and urge incontinence, which can be complicated by urinary retention if the urethral sphincter fails to relax as the bladder contracts (Wyndaele et al., 2005). Deficiencies in neurotransmission that occur with Parkinson's disease can lead to overactive bladder symptoms or to a hypocontractile bladder. Conditions affecting the peripheral nervous system, such as diabetes mellitus, generally cause impaired bladder contractility, reduced sensation of bladder fullness, and incomplete emptying (Wyndaele et al., 2005).

Patients with cognitive impairment, such as Alzheimer's disease, may lose the ability to sense a full bladder or may be unable to recall the procedure for voiding (Dubeau et al., 2009). Diseases or conditions that slow or hinder mobility also interfere with the physical act of micturition. A patient with rheumatoid arthritis, for example, may be unable to sit on or rise from a toilet without an elevated toilet seat.

Conditions that affect the volume or quality of the urine are generally categorized as prerenal, renal, or postrenal in origin. Prerenal alterations such as dehydration, hemorrhage, and heart failure decrease circulating blood flow to and through the kidneys and can lead to **oliguria** (diminished capacity to form urine) or, less commonly, **anuria** (inability to produce urine). Renal alterations result from conditions such as diabetes mellitus that cause injury directly to the glomeruli or renal tubule, interfering with their normal filtering, reabsorptive, and secretory functions. Postrenal alterations result from obstruction to the flow of urine in the urinary collecting system anywhere between the renal pelvis and the urethral meatus. Urine is formed by the urinary system but cannot be eliminated by normal means. Obstructive symptoms in the male lower urinary tract, such as hesitancy, intermittent stream, and straining to void, are frequently associated with enlargement of the prostate gland caused by benign prostatic hyperplasia or prostate cancer.

Diseases and conditions that cause irreversible damage to the glomeruli or renal tubules cause permanent alterations in renal function. The resulting decline in kidney function is called end stage renal disease, and the patient manifests numerous metabolic disturbances that necessitate treatment for survival. The associated symptoms occur as a result of the **uremic syndrome**, characterized by an increase in nitrogenous wastes in the blood, altered regulatory functions (causing marked fluid and electrolyte abnormalities), nausea, vomiting, headache, coma, and convulsions. The problem may be managed conservatively with medications and a regimen of dietary and fluid restrictions. However, as the uremic symptoms worsen, more aggressive treatment is indicated. These treatments are known as **renal replacement therapies**.

Renal Replacement Therapies. Dialysis (Box 43-1) and organ transplantation are two methods of renal replacement. Dialysis may take one of two forms: peritoneal or hemodialysis. Both dialysis modalities can be applied for a short or long time, but specialized equipment and nurses with specific training must be available.

Peritoneal dialysis is an indirect method of cleansing the blood of waste products using osmosis and diffusion. The

► BOX 43-1 Indications for Dialysis

Renal failure that can no longer be controlled by conservative management (i.e., dietary modifications and administration of medications to correct electrolyte abnormalities)

Worsening of uremic syndrome associated with end-stage renal disease (i.e., nausea, vomiting, neurological changes, pericarditis)

Severe electrolyte or fluid abnormalities that cannot be controlled by simpler measures (i.e., hyperkalemia, pulmonary edema)

peritoneum functions as a semipermeable membrane. Excess fluid and waste products are readily removed from the bloodstream when a sterile electrolyte solution (dialysate) is instilled into the peritoneal cavity by gravity via a surgically placed catheter. The dialysate is left in the cavity for a prescribed time interval and then drained out by gravity, taking accumulated wastes and excess fluid and electrolytes with it.

Hemodialysis involves using a machine equipped with a semipermeable filtering membrane (artificial kidney) that removes accumulated waste products and excess fluids from the blood. In the dialysis machine, dialysate fluid is pumped through one side of the filter membrane (artificial kidney) while the patient's blood passes through the other side. The processes of diffusion, osmosis, and ultrafiltration cleanse the patient's blood, which is returned through a specially placed vascular access device (Gore-Tex graft, arteriovenous fistula, or hemodialysis catheter).

Organ transplantation is the replacement of a patient's diseased kidney with a healthy one from a living or cadaver donor of compatible blood and tissue type. The new organ is surgically implanted into the abdomen. Special medications (immunosuppressives) are administered for life to prevent the body from rejecting the transplanted organ. Unlike dialysis, successful organ transplantation offers the patient the potential for restoration of normal kidney function.

Fluid Balance. Fluid balance directly affects the quantity of urine produced. The kidneys maintain a sensitive balance between retention and excretion of fluids (see Chapter 39). If fluids and the concentration of electrolytes and solutes are in equilibrium, an increase in fluid intake causes an increase in urine production. Ingested fluids increase the body's circulating plasma and thus increase the volume of urine excreted. In a healthy person, the intake of water in food and fluids balances the output of water in urine, feces, and insensible losses through perspiration and respiration. An excessive output of urine is known as **polyuria**, a common symptom of diabetes mellitus and diabetes insipidus.

Ingestion of certain fluids directly affects urine production and excretion. Coffee, tea, cocoa, and cola drinks that contain caffeine promote increased urine formation (**diuresis**). Alcohol inhibits the release of antidiuretic hormone (ADH), resulting in increased water loss in urine.

Febrile conditions also affect urine production. The patient who becomes diaphoretic (sweats profusely) loses a large amount of fluid through insensible water loss, which decreases urine production. However, the increased body metabolism associated with fever increases accumulation of body wastes. Although urine volume may be reduced, it is highly concentrated.

Medications. Medications may interfere with the production of urine and affect the act of urination. Diuretics

prevent reabsorption of water and certain electrolytes, resulting in a sudden increase in urine output that can challenge continence. Drugs with anticholinergic side effects such as tranquilizers or tricyclic antidepressants, anti-arrhythmics, sedating antihistamines, anti-Parkinsonian agents, and antispasmodics relax the bladder and can contribute to incomplete emptying and urinary retention (Mostwin et al., 2005). The drug-induced cough associated with angiotension-converting enzyme (ACE) inhibitors can precipitate stress incontinence. You must be aware of any prescribed and over-the-counter medications a patient is taking and how these medications may affect bladder function. Patients with altered kidney function require dosage modifications in any medications excreted by the kidneys.

Diagnostic Examination. Examination of the urinary system can influence micturition. Procedures such as an intravenous pyelogram may necessitate that the patient limit fluid intake before the test. A restriction in fluid intake commonly lowers urine output. A laxative used to cleanse the bowel also may limit fluid available for urine production. Diagnostic examinations (i.e., cystoscopy) that involve direct visualization of urinary structures may cause localized edema of the urethral passageway and spasm of the striated muscle. The patient often has urinary retention after such a procedure and may pass red or pink urine because of trauma to the urethral or bladder mucosa.

Surgical Procedures. The stress of surgery initially triggers the general adaptation syndrome (see Chapter 29). The surgical patient is often in an altered state of fluid balance before surgery due to the disease process or preoperative fasting, which aggravates the reduction in urine output. The stress response releases an increased amount of ADH, which increases water reabsorption. Stress also elevates the level of aldosterone, causing retention of sodium and water. Both of these substances reduce urine output in order to maintain circulatory volume. The decreased blood pressure after surgery releases renin and thus increases angiotensin II to increase vascular tone. This aids in counteracting the effects of ADH and aldosterone.

Anaesthetics and narcotic analgesics may alter the glomerular filtration rate (generally 125 mL/minute), reducing urine output. These pharmacological agents also impair sensory and motor impulses travelling between the bladder, spinal cord, and brain. Patients recovering from anaesthesia and deep analgesia are often unable to sense bladder fullness and unable to initiate or inhibit micturition. Spinal and epidural anaesthetics, in particular, may cause urinary retention because the patient cannot feel the need to void and the bladder muscle and sphincter may not respond (Sherwood, 2007).

Surgery involving lower abdominal and pelvic structures can impair urination because of local trauma to surrounding tissues. The edema and inflammation may obstruct the flow of urine from the kidneys to the bladder or from the bladder or urethra, interfere with relaxation of pelvic and sphincter muscles, or cause discomfort during voiding. After returning from surgery involving the ureters, bladder, and urethra, patients routinely have catheters.

The surgical formation of a **urinary diversion** temporarily or permanently bypasses the bladder and urethra as the exit routes for urine. Permanent urinary diversions may be needed in the patient with cancer of the bladder. The patient with a urinary diversion has a **stoma** (artificial opening) on the abdomen through which urine is drained.

Psychological Factors. Anxiety and emotional stress may cause a sense of urgency and increased frequency of urination. Anxiety also may prevent a person from being able to urinate completely; as a result, the urge to void may return shortly after urinating. Emotional tension makes it difficult to relax the abdominal and perineal muscles. If the sphincter is not completely relaxed, voiding may be incomplete.

Attempting to void in a public restroom also may result in a temporary inability to urinate. Privacy and adequate time to urinate are important to most people, and some may need distractions to help them relax (e.g., reading). The possibility that incomplete voiding may result from physiological abnormalities, however, must always be considered.

Common Alterations in Urinary Elimination

Most patients with urinary problems have disturbances in the act of micturition that involve a failure to store urine, a failure to empty urine, or both. Disturbances may be acute or chronic and result from infection, impaired bladder function, obstruction to urine outflow, or inability to control micturition voluntarily.

Urinary Tract Infections. Urinary tract infections (UTIs) are responsible for more than 500,000 visits to Canadian doctors every year (Kidney Foundation of Canada, 2007). If left untreated, UTIs can spread to the kidneys, causing kidney infection (**pyelonephritis**) and possibly long-term kidney damage.

Etiology. Although several different microorganisms may cause UTIs, *Escherichia coli* is the most frequent causative pathogen, accounting for 80% of uncomplicated infections. Between 10% and 20% of UTIs are caused by *Staphylococcus saprophyticus*, and approximately 5% are caused by *Klebsiella*, *Proteus*, and *Enterobacter* organisms.

Bacteria in the urine (**bacteriuria**) may lead to the spread of organisms into the kidneys and the bloodstream, leading to **urosepsis**. Bacteria usually enter the urinary tract by ascending the urethra. They inhabit the distal urethra, external genitalia, and vagina in women. Organisms enter the urethral meatus easily and travel up the inner mucosal lining to the bladder. Women are more susceptible to infection because of the short urethra and the proximity of the vaginal vestibule and rectum to the urethral meatus (Nguyen, 2008).

Infection depends on the virulence of the bacteria and the presence of host defence mechanisms. In a healthy person with good bladder function, organisms are flushed from the body during voiding. Normal urine has a low pH, which inhibits bacterial growth.

Although the short length of the female urethra makes women more susceptible to UTIs, organisms such as *Lactobacillus* that occur naturally in the periurethral area inhibit colonization of pathogenic bacteria. In addition, mucus-secreting glands found in the distal two-thirds of the female urethra impede bacterial ascension. In men, the length of the urethra and the presence of zinc, a powerful antimicrobial substance found in prostatic secretions, reduce susceptibility (Nguyen, 2008).

Alterations in any of these defence mechanisms can contribute to a UTI. For example, if the patient cannot empty the bladder when voiding or the free flow of urine is impeded, **residual urine** (urine left in the bladder after voiding) becomes more alkaline and is an ideal site for microorganism growth. Therefore, a kinked, obstructed, or clamped catheter or any condition resulting in urinary retention increases the risk of

bladder infection. Risk factors for urinary infection in women include sexual activity, pregnancy, diaphragm or spermicide use, and pelvic organ prolapse. UTIs are less common in men; risk factors include the introduction of instruments into the urinary tract (instrumentation) and congenital abnormalities (Nguyen, 2008). Older adults, patients using antibiotics, and patients with progressive underlying disease or decreased immunity are also at increased risk. Changes associated with aging, including **prostatic hypertrophy** and diminished bacteriocidal activity of prostatic secretions in men, and diminished estrogen in women, predispose older adults to bacteriuria (Juthani-Mehta, 2007). Prostatic hypertrophy, the enlargement of the prostate gland, is particularly troubling, as it can lead to obstruction of the urethral outlet and affects approximately 80% of men in their eighties. Patients with diabetes mellitus are especially susceptible to UTIs because increased glucose in the urine is a good medium for bacterial growth.

One of the most common causes of UTI, however, is instrumentation. UTIs account for nearly half (40%) of nosocomial, or hospital-acquired, infections (Saint et al., 2008). The introduction of a catheter through the urethra provides a direct route for microorganisms. Bacteria ascend along the outside of an indwelling catheter on the urethral wall or travel up the catheter's lumen, and bacteriuria is generally inevitable within two days. One hundred percent colonization can be expected after 30 days. Local irritation to the urethra or bladder also predisposes tissues to bacterial invasion. Catheter-related bacteriuria has been associated with a twofold to threefold increase in risk of death among hospitalized patients (Cottenden et al., 2005).

Signs and Symptoms. Patients with lower UTIs may experience pain or a burning sensation during urination (**dysuria**) as urine flows over inflamed tissues. Fever, chills, nausea, vomiting, and malaise may develop as the infection worsens. Inflammation of the bladder (**cystitis**) causes a frequent and urgent sensation of the need to void, and may cause **incontinence**. Irritation to bladder and urethral mucosa results in blood tinged urine (**hematuria**). The urine appears concentrated and cloudy because of the presence of white blood cells (WBCs) or bacteria. If infection spreads to the upper urinary tract (i.e., to the kidneys, causing pyelonephritis), rapid onset of flank or lower back pain, tenderness, fever, and chills can occur.

Lower UTIs also can be asymptomatic, particularly in pregnant women, children, and older adults. Asymptomatic UTIs generally are not treated in older adults, in part because no evidence of short-term or long-term adverse effects or impact on survival exists (Juthani-Mehta, 2007).

Urinary Incontinence. **Urinary incontinence (UI)** is the involuntary loss of urine (Abrams et al., 2002). It is a prevalent condition experienced by more than 3 million Canadians of all ages (Canadian Continence Foundation, 2007). Psychosocial impact ranges from minor lifestyle changes to self-imposed social isolation.

Urinary incontinence may present as any of the following types (Registered Nurses' Association of Ontario [RNAO], 2005):

- **Transient incontinence:** urine loss resulting from causes outside of or affecting the urinary system that resolves when the underlying causes are treated. Causes include dementia or acute confusion, infection (symptomatic UTI), atrophic urethritis or vaginitis in women, pharmaceuticals (medications), endocrine disorders, restricted mobility, and

stool impaction (DIAPERS).^{*} A more optimistic acronym—DISAPPEAR—has been proposed by Whytock (2006): *delirium, intake of fluids, stool impaction, atrophic vaginitis, psychological problems (depression), pharmaceuticals, excess urine output, abnormal lab values (e.g., hyperglycemia), and restricted mobility.*

- **Urge incontinence:** urine loss associated with or immediately preceded by a sudden and urgent need to void that cannot be postponed. Individuals with urge incontinence generally present with **urinary frequency** (need to void more often than every two hours) and **nocturia** (voiding overnight). Causes include nervous system disorders (cerebrovascular accident, multiple sclerosis) and outflow obstruction, particularly in men with an enlarged prostate, but urge incontinence also may be idiopathic (of unknown origin).
- **Stress incontinence:** generally small volume (<50 mL) urine loss resulting from increased intra-abdominal pressure (e.g., coughing, sneezing, laughing, lifting). Stress incontinence is most common in women and in men after radical prostatectomy. Weak pelvic floor muscles and supportive tissue, obesity, and lifestyle factors such as heavy lifting are contributing factors.
- **Mixed incontinence:** urine loss that has features of both stress and urge incontinence.
- **Functional incontinence:** urine loss caused by alterations in cognitive or physical function or by environmental factors. The person has bladder control but is unable to reach the toilet. Causes may include confusion, difficulty removing clothing, or immobility. Older patients with restricted mobility are at high risk.
- **Overflow incontinence:** small or large amounts of urine loss associated with overdistension of the bladder. The person may feel as if the bladder is never completely empty. Overflow incontinence may be associated with bladder outlet obstruction, fecal impaction, diabetes, spinal cord injury, prostate enlargement, or severe uterine prolapse.
- **Reflex incontinence:** involuntary urine loss that occurs at somewhat predictable intervals. The person is unaware that the bladder is filling and does not feel the urge to void, but the bladder contracts spontaneously. Reflex incontinence may be caused by spinal cord dysfunction (inhibition of cerebral awareness or impairment of the reflex arc).
- **Total incontinence:** continuous and unpredictable loss of urine caused by damage to the nerves that control the bladder. It may be a result of spinal deformities such as spina bifida or scoliosis, spinal cord injury, or advanced disease such as multiple sclerosis or Alzheimer's disease. Repeated pelvic surgery also may cause total incontinence from scarring of the urethra.

safety alert Continued episodes of incontinence create the potential for skin breakdown. The immobilized patient who experiences frequent incontinence is especially at risk for pressure ulcers (see Chapter 46). Timely and meticulous skin care is essential.

Overactive Bladder Syndrome. Overactive bladder syndrome (OAB) is a symptom-based syndrome characterized predominantly by the presence of urgency, the sudden and compelling desire to void that is difficult to postpone (Abrams

et al., 2002). Approximately 16% to 18% of adults experience OAB; one-third of these adults also experience urge incontinence. Similar to urge incontinence, OAB can be idiopathic but is commonly attributed to changes associated with nervous system disorders and outflow obstruction. OAB may be aggravated by caffeinated beverages, although effects appear to be dose-dependent (Getliffe & Fader, 2007).

Nocturia. Nocturia has been defined as waking at night to void (Fonda et al., 2005). It is associated with aging and an overactive bladder, as well as with an enlarged prostate in men. Patients with peripheral edema (e.g., caused by circulatory problems associated with venous insufficiency) may experience nocturia because lying down facilitates reabsorption of pooled fluid and leads to increased urinary output overnight (Mostwin et al., 2005). Causes are generally categorized as **diurnal polyuria** (excessive production of urine during the day, as can occur with diabetes mellitus or diabetes insipidus), **nocturnal polyuria** (at least one-third of total daily urine production occurs overnight), or low bladder capacity (Appell & Sand, 2008). The latter may be due to an overactive bladder or a compromised urethral closure that affects urine storage, or to reduced functional capacity.

Regardless of the cause, it is important to learn whether a patient wakes at night to void, or voids because he or she is awake. Treatment options include reducing fluid intake in the evening, elevating the feet for one to two hours before bedtime to encourage return of fluid from the lower extremities, medication to reduce the volume of urine produced overnight, or medication to relax the bladder muscle.

Urinary Retention. Urinary retention is the marked accumulation of urine in the bladder as a result of the bladder's inability to empty. Normally, urine production slowly fills the bladder and prevents activation of stretch receptors until the bladder distends to a certain extent. The micturition reflex then occurs, and the bladder empties. With urinary retention, the bladder becomes unable to respond to the micturition reflex and thus is unable to empty. Urine continues to collect in the bladder, causing feelings of pressure, discomfort, tenderness over the symphysis pubis, restlessness, and diaphoresis. As retention progresses, overflow incontinence may occur. Pressure in the bladder builds to a point at which the urethral sphincter is unable to hold back urine and a small volume escapes (<75 mL). The patient may void small amounts of urine two or three times an hour with little relief of discomfort.

Urinary retention results from an underactive or acontractile detrusor muscle, urethral obstruction (more common in men and usually related to prostatic enlargement), surgical or childbirth trauma, alterations in motor and sensory innervation of the bladder, medication side effects (e.g., anticholinergics), or fecal impaction. **Urethral stricture**, a narrowing of the urethral canal that can be congenital or acquired as a result of infection or trauma, is also a more common cause of urinary retention in men.

You should be aware of the volume and frequency of voiding to assess this condition in the patient. Key signs of urinary retention are absence of urine output over several hours, bladder distension, restlessness, diaphoresis, and moderate to extreme abdominal discomfort. A patient under the influence of anaesthetics or analgesics may feel only pressure, but an alert patient experiences severe pain as the bladder distends beyond its normal capacity. In severe urinary retention, the bladder may hold as much as 2000 to 3000 mL of urine.

^{*}The acronym DIAPERS was coined by Resnick (1984) to help clinicians remember the causes, but it is not used in medical notes.

Figure 43-5 Types of urinary diversions.

Intermittent catheterization may be needed to empty the bladder and reduce the risk of overflow incontinence and UTI.

Urinary Diversions. A urinary stoma to divert the flow of urine from the kidneys directly to the abdominal surface is created for several reasons, including cancer of the bladder, trauma, radiation injury to the bladder, fistulas, and chronic cystitis. A urinary diversion may be temporary or permanent. The patient with an incontinent urinary diversion must wear an ostomy appliance continuously because no sphincter control exists to regulate urine flow. Local irritation and skin breakdown occur when urine comes in contact with the skin for long periods. Figure 43-5 illustrates several approaches to urinary diversion.

The ileal loop or conduit involves separating a loop of intestinal ileum with its blood supply intact. The ureters are implanted into the isolated segment of ileum. The remaining ileum is reconnected to the rest of the digestive tract. The ileal segment can then be used as a conduit for continuous urine drainage or fashioned into a continent reservoir (Konety et al., 2008). The continent pouch is constructed to provide urinary storage in a leak-proof pouch. The portion of the ileum connected to the abdominal wall acts as a continent nipple, and intermittent catheterization is therefore needed for emptying. The disadvantage of an ileal conduit or reservoir is that if urine outflow becomes obstructed, irreversible damage to the kidneys can occur secondary to chronic infections or hydronephrosis.

A **ureterostomy** involves bringing the end of one or both ureters to the abdominal surface. To avoid the need for two collecting devices, a transureteroureterostomy connects the ureters and brings one out through the abdominal wall. In some cases, a tube may need to be placed directly into the renal pelvis to provide urinary drainage. This procedure is called a **nephrostomy**.

It is essential that stoma appliances fit correctly, that the patient (or caregiver) is capable of changing the appliance easily, and that skin around the stoma remains protected and intact. Unprotected skin that comes in contact with urine will

quickly become macerated and break down, causing pain, infection, increased hospital stays, and potential breakdown of the stoma. All patients must be referred to an enterostomal nurse for preoperative stoma fitting and assessment and should be followed closely for several months postoperatively. The patient should also be referred to the United Ostomy Association of Canada, an invaluable source of advice and networking.

A urinary diversion poses threats to a patient's body image, and adjustment to it takes time. Although a normal lifestyle is possible with a stoma, adjustment can be difficult and each person will cope differently.

Nursing Knowledge Base

Urinary elimination is a basic human function that is usually a private process. Nurses are often the first to become aware that a patient has elimination problems and must be alert to cues, prepared to discuss relevant assessment and treatment options, and able to provide counselling and support. These skills require a sound base of scientific knowledge related to anatomy and physiology, as well as an understanding of concepts such as infection control and hygiene, normal growth and development, and psychosocial and cultural considerations.

Infection Control and Hygiene

The urinary tract is considered to be sterile. You must use infection-control principles to help prevent the development and spread of UTIs, as well as to treat existing infections (see Chapter 32). Hospital-acquired UTIs are often related to poor hand hygiene, improper catheter care, or faulty catheterization technique (Nguyen, 2008). Knowledge of both medical and surgical asepsis must be applied meticulously when providing care involving the urinary tract and external genitalia. Any invasive procedure of the urinary tract such as catheterization necessitates sterile technique. Procedures such as perineal care or examination of the genitalia necessitate medical asepsis.

Growth and Development

Growth and development factors determine the patient's ability to control the act of urination during the lifespan. Infants and young children cannot concentrate urine effectively. Their urine appears light yellow and clear.

Relative to their small body size, infants and children excrete large volumes of urine. For example, a six-month-old infant who weighs 6 to 8 kg excretes 400 to 500 mL of urine daily. As the neurological system matures, a toddler of two to three years of age is able to associate the sensations of bladder filling and urination. A child must be able to recognize the feeling of bladder fullness, hold urine for one to two hours, and communicate the sense of urgency to an adult. Many toddlers may then be able to control the urethral sphincter, and toilet training can begin. Young children need their parents' understanding, patience, and consistency. A child may not gain full control of micturition until four or five years of age. Daytime control of micturition is easier to accomplish than nighttime control and occurs earlier in the child's development, usually by two years of age. Occasional daytime accidents or nocturnal enuresis (bedwetting) may continue until five years of age.

The adult normally voids 1500 to 1600 mL of urine daily, or approximately 500 mL every four hours. During pregnancy,

urinary frequency is common and susceptibility to UTIs is increased. In women, childbearing and hormonal changes during menopause may contribute to urinary difficulties. In men, prostate enlargement can begin in the forties and continue throughout the lifespan, resulting in urinary frequency and possibly retention.

Changes in kidney and bladder function also occur with aging. The kidney's ability to concentrate urine or reabsorb water and sodium declines. Alterations in kidney function include a reduction in glomerular filtration rate, from 125 mL per minute in younger adults to 60 to 70 mL per minute in adults 80 years of age. The older adult often experiences nocturia, due in part to age-related changes in vasopressin secretion (Fonda et al., 2005). The functional capacity of the bladder decreases, resulting in increased urinary frequency. Detrusor contractility also decreases, contributing to less effective emptying, elevated postvoid residuals (the volume remaining in the bladder after a void), and increased susceptibility to UTIs. A decrease in urethral closure pressure in women, which is generally associated with a decline in estrogen levels, can contribute to an increase in incontinence (Fonda et al., 2005). Older men commonly experience incomplete bladder emptying associated with prostatic enlargement.

Psychosocial and Cultural Considerations

You must consider that urinary elimination problems may result in alterations of sexuality and self-concept (which includes body image, self-esteem, roles, and identity). The embarrassment associated with elimination problems may delay or prevent help seeking. Individuals with incontinence often blame themselves for their condition and go to great lengths, including self-imposed social isolation, to keep others from finding out about it. Nurses must therefore initiate discussion by asking patients if they are experiencing any issues related to urinary elimination or bladder control as a routine part of care. It is also important to determine how bothersome symptoms are for each patient before planning care. The patient and clinician may have different perceptions of the severity of symptoms (Avery et al., 2007) so it is important to understand a patient's goals and expectations for treatment to ensure that interventions are realistic.

Sociocultural factors may influence the patient's expectation of the degree of privacy and location for attending to urinary needs. Your approach to a patient's elimination needs must consider cultural, social, and gender habits. If a patient prefers privacy, try to prevent interruptions as the patient voids. A patient with less need for privacy should also be treated with understanding and acceptance. Ensure that the patient is comfortable when he or she is trying to void. In some cultures, people prefer to squat over a receptacle rather than sit on one. Culture dictates when and where it is appropriate to urinate. In some cultures, a woman with urinary needs should be assisted only by another woman.

Critical Thinking

Critical thinking during assessment of urinary elimination requires the integration of evidence-informed knowledge from nursing and other disciplines, experiential knowledge, and an understanding of the patient's perceptions of the alterations in elimination and their impact. Critical thinking also involves an understanding of relevant cultural, environmental, and personal factors, including the unique goals of every patient. Empathy, teaching, and ongoing support are needed

to assist the patient in meeting these goals and maintaining improvement.

Professional standards provide valuable directions for treatment and management of elimination problems. When planning and implementing care for the patient with alterations in urinary elimination, use the standards developed by professional organizations such as the Canadian Nurses Association, the Canadian Nurse Continence Advisors, the Canadian Continence Foundation, the United Ostomy Association of Canada, and the Urology Nurses of Canada.

Nursing Process and Alterations in Urinary Function

Assessment

To identify a urinary elimination problem and gather data for a care plan, you obtain information by collecting a health history, performing a focused physical assessment, assessing the patient's urine, and reviewing information from diagnostic tests and examinations. Use critical thinking to synthesize this information as assessment proceeds (Figure 43-6). Adequate

Figure 43-6 Critical thinking model for urinary elimination assessment.

assessment should result in the formulation of nursing diagnoses appropriate for alterations in urinary elimination. You should be alert to individual needs related to normal aging that predispose older adults to certain elimination problems (Box 43-2).

* BOX 43-2 FOCUS ON OLDER ADULTS

- Physiological changes in the lower urinary tract occur in continent as well as incontinent older adults.
- Dilute urine discourages bacterial growth; therefore, older adults should be encouraged to increase their fluid intake to at least six glasses a day, unless medically contraindicated (Dubeau et al., 2009).
- Fluids that promote an acidic urine (e.g., cranberry juice) should be made available as part of the patient's fluid intake because an acidic urine also helps to inhibit bacterial growth and may prevent UTIs (Nguyen, 2008).
- Restriction of fluids two hours before sleep, combined with elevating the legs to allow for venous return and bladder emptying before bedtime (leg elevation for at least one hour) may decrease the incidence of nocturia (Dubeau et al., 2009).
- In-dwelling catheters should not be used routinely in older adults unless other options have been tried. The risk of infection increases dramatically for catheterized patients (Juthani-Mehta, 2007).
- Treating asymptomatic bacteriuria in older adults is not recommended.
- Incontinence is not a normal part of aging, and efforts should be made to assess incontinence and provide interventions to promote return to continence.

Health History

The nursing health history includes a review of the patient's urinary elimination patterns and symptoms of urinary alterations and an assessment of factors that may affect the ability to urinate normally.

Pattern of Urination. Ask the patient about usual daily voiding patterns and any recent changes. Information about voiding symptoms such as hesitancy (Table 43-1) and the overall pattern of urination, including average time between voids and episodes of urgency and incontinence, is important to a nursing assessment and establishes a baseline for comparison.

A **urinary diary** is an important diagnostic tool (Figure 43-7), particularly because many adults are not aware of how often they void throughout the day. A diary is kept by the patient or the caregiver; it records approximate times of urination, times of leakage and estimates of the amount lost (dribbled, wet pad, wet clothing), and types and amount of fluids ingested. Measuring two or more voids (not including the first void of the morning) will provide useful information about the volume of urine that a patient generally stores. Recording factors that precipitated urination or leakage, such as a strong urge or a cough, is particularly helpful. The number of pad changes per day is also useful information. A three-day (72-hour) voiding diary helps in evaluating lifestyle habits (e.g., fluid intake) in relation to the voiding pattern and symptoms (Ermer-Seltun, 2006).

Factors Affecting Urination. It is important to summarize the factors associated with the patient's medical history, surgical history, and current environment that may affect urination. Medical history includes disease conditions that can affect elimination, such as multiple sclerosis, spinal cord injury, stroke, and diabetes. Another factor to consider is the patient's

► TABLE 43-1 Common Symptoms of Urinary Alterations

Symptom	Description	Common Causes or Associated Factors
Incontinence	Involuntary loss of urine	Multiple factors: urethral hypermobility, loss of pelvic floor muscle tone, fecal impaction, neurological impairment, pelvic organ prolapse
Urgency	Sudden and compelling urge to void that cannot be postponed	Overactive bladder syndrome that is neurogenic, sensory, or idiopathic; calculi or tumour; urinary tract infection (UTI)
Dysuria	Painful or difficult urination	Bladder inflammation; urethral trauma; UTI; inflammation of urethra, sphincter, or both
Frequency	Voiding more than eight times in 24 hours	Increased fluid intake, bladder infection or inflammation, increased pressure on bladder (pregnancy, psychological stress), incomplete emptying, small bladder capacity, overactive bladder syndrome, polyuria
Hesitancy	Difficulty initiating urination	Hypotonic bladder, anxiety, urethral stricture, obstruction associated with prostate enlargement
Polyuria	Voiding large amounts of urine	Excess fluid intake, diabetes mellitus or diabetes insipidus, use of diuretics, postobstructive diuresis
Oliguria	Diminished urinary output relative to intake (usually 400 mL/24 hours)	Dehydration, renal failure, increased antidiuretic hormone (ADH) secretion, heart failure
Nocturia	Getting up at night to void	Excessive fluid intake before bed (especially coffee or alcohol), renal disease, aging process, cardiovascular insufficiency, prostate enlargement, sleep apnea
Dribbling	Leakage of urine despite voluntary control of urination	Stress incontinence, overflow from urinary retention, postvoid pooling of urine in the urethra (men)
Hematuria	Blood in the urine	Neoplasms of the kidney or bladder, glomerular disease, infection of kidney or bladder, trauma to urinary structures, calculi, bleeding disorders, UTI
Retention	Accumulation of urine in the bladder, with inability of bladder to empty fully	Urethral obstruction, bladder inflammation, decreased sensory activity, neurogenic bladder, prostate enlargement, postanaesthesia effects, side effects of medications (e.g., anticholinergics, antidepressants)
Elevated postvoid residual urine	Elevated volume of urine remaining after voiding (>100 mL)	Neurogenic bladder, prostate enlargement, trauma, inflammation of urethra, inflammation or irritation of bladder mucosa from infection

Bladder Diary DAY 1

Figure 43-7 Sample urinary diary. **Source:** Canadian Continence Foundation. (2010). *The source: Your guide to better bladder control* (pp. 12–13). Peterborough, ON: Author. Retrieved from <http://www.canadiancontinence.ca/pdf/The-Source.pdf>.

bowel elimination pattern. Constipation often interferes with normal urine elimination. Medication history, including the name, amount, and frequency of each prescription and over-the-counter medication, should also be noted as part of the medical history.

Relevant surgical history (e.g., urological and gynecological interventions, pelvic radiation) should be considered because surgery may cause scarring and disruption of neurological pathways. The presence or history of an in-dwelling catheter should be noted because of the potential for infection, catheter blockage, or skin care problems. Environmental barriers in the home or health care setting also should be evaluated. The patient's mobility and ability to dress or undress and use the toilet independently should be assessed. Such aids as elevated toilet seats, grab bars, or a portable commode may be needed.

One of the most important parts of the assessment is the impact of alterations in elimination on the patient's lifestyle and quality of life. The impact of urinary incontinence in particular can be substantial; it is important to discuss changes the patient has made to cope with the condition. It is also

important to note whether the patient has previously seen a health care provider for help with or advice on urination.

Physical Assessment

A physical examination (see Chapter 31) provides you with data with which you can determine the presence and severity of urinary elimination problems. The primary structures reviewed are the skin and mucosal membranes, kidneys, bladder, and perineum.

Skin and Mucosal Membranes. Assess the condition of the skin and mucosal membranes. Problems with urinary elimination are often associated with fluid and electrolyte disturbances. By assessing skin turgor and the oral mucosa, you assess the patient's hydration status. Urinary incontinence increases the risk of skin breakdown (see Chapter 46).

Kidneys. Flank pain usually develops if the kidneys become infected or inflamed. Assess for flank tenderness early in the disease by percussing the costovertebral angle (the angle formed by the spine and the twelfth rib). Auscultation is also performed to detect the presence of a renal artery bruit (sound

resulting from turbulent blood flow through a narrowed artery).

Nurses with advanced examination skills learn to palpate the kidneys during abdominal examination. The kidneys' position, shape, and size can reveal renal swelling.

Bladder. In adults, the bladder rests below the symphysis pubis and is difficult to palpate. When distended, the bladder rises above the symphysis pubis at the midline of the abdomen and may extend to just below the umbilicus. On inspection, you may note a swelling or convex curvature of the lower abdomen. You should lightly palpate the lower abdomen. The partially filled bladder normally feels smooth and rounded. As you apply light pressure to the bladder, the patient may feel the urge to urinate, tenderness, or even pain. Percussion of a full bladder yields a dull note.

The Female Perineum. When examining the female patient, request that she assume a dorsal recumbent position to provide full exposure of the genitalia. Inspect the perineum for skin integrity and for the presence of a rash associated with incontinence and the use of containment pads. The rash may be monilial (maculopapular, red rash) or an ammonia contact perineal dermatitis (papular with macerated skin).

Assess the vaginal vault for signs of vaginitis, a common result of estrogen depletion after menopause (Mostwin et al., 2005). Signs include dry, thin, pale mucosa; erosions; and tenderness or sensitivity to touch. Inspect the vaginal orifice carefully for signs of inflammation and describe any drainage.

Also, assess the urethral meatus and note the presence of any discharge, inflammation, or lesions. Normally the meatus is pink and appears as a small, slitlike opening below the clitoris and above the vaginal orifice. It may recede well into the vaginal vault with aging, making catheterization difficult. Discharge from the meatus is normally not present. If it is present, specimens of urethral discharge should be obtained before the patient voids.

Pelvic floor muscle strength can be digitally assessed in women by gently inserting a gloved finger into the vagina. Ask the patient to squeeze around your finger as firmly as possible, and then hold the contraction (generally for three to five seconds). Digital assessment is very useful in helping the patient to identify the pelvic floor muscles correctly.

The Male Perineum. The male urethral meatus normally appears as a small opening at the tip of the penis. You should inspect the meatus for any discharge, inflammation, or lesions. If the foreskin needs to be retracted in uncircumcised men to see the meatus, it must be replaced to avoid constriction of the glans. Disposable gloves should be worn when retracting the foreskin. Pelvic floor muscle strength can be digitally assessed in men by gently inserting a gloved finger into the rectum and asking the patient to squeeze around it.

Assessment of Urine

Assessment of urine involves measuring the patient's fluid intake and urine output and observing characteristics of the urine.

Intake and Output. It is important to assess the patient's average daily fluid intake. If an accurate measurement of fluid intake is needed from the patient who is at home, ask him or her to show a commonly used glass or cup on which the intake estimate is based. In a health care setting, measure a patient's fluid intake either when the physician orders intake and output measurements or when nursing judgement warrants a more precise measurement (see Chapter 39). A change in urine

volume is a significant indicator of fluid alterations or kidney disease. While caring for the patient, assess urine volume by measuring output with each voiding (using plastic receptacles, bedpans, or urinals). Special receptacles (urimeters) attach between in-dwelling catheters and drainage bags and are a convenient means of accurately measuring urine volume. A urimeter holds 100 to 200 mL of urine. After measuring urine with a urimeter, you can drain the cylinder into the urinary drainage bag or into a receptacle for disposal. Urimeters are indicated when precise hourly measurements of urine are needed.

When urine from a drainage bag is measured, the urine should be drained into a plastic graduated receptacle for more precise measurement of output (Figure 43-8). Each patient should have a graduated receptacle for his or her exclusive use to prevent potential cross-contamination.

You should report any extreme increase or decrease in urine volume. An hourly output of less than 30 mL for more than two hours is cause for concern. Similarly, consistently high volumes of urine (polyuria), over 2000 to 2500 mL daily, should be reported to a physician.

Characteristics of Urine. You will inspect the patient's urine for colour, clarity, and odour.

Colour. Normal urine ranges from a pale, straw colour to amber, depending on its concentration. Urine is usually more concentrated in the morning or with fluid volume deficits. As a person drinks more fluids, urine becomes less concentrated.

Bleeding from the kidneys or ureters causes urine to become dark red; bleeding from the bladder or urethra causes urine to become bright red. Various medications and foods also change

Figure 43-8 Urine drainage bag.

▶ TABLE 43-2 Urine Testing

**Collection Type (Use of Specimen)**

Random specimen (routine urinalysis)

Clean-voided or midstream specimen (culture and sensitivity)

Sterile specimen (culture and sensitivity)

Timed urine specimens (for measuring levels of adrenal cortical steroids or hormones, creatinine clearance, or protein quantity tests)

Nursing Considerations

Can be collected during normal voiding, from an in-dwelling catheter or a urinary diversion collection bag. Collected in a clean specimen cup.

See Skill 43-1. Collected in a sterile specimen cup.

If the patient has an in-dwelling catheter, a sterile specimen can be collected using the aseptic technique through the special port (see Figure 43-9) found on the side of the catheter. If the catheter has been in situ for more than three days, it should be changed before the specimen is collected to avoid contamination by organisms in the catheter lumen.

Clamp the tubing below the port, allowing fresh, uncontaminated urine to collect in the tube. After wiping the port with an antimicrobial swab, insert a sterile syringe needle and withdraw at least 3 to 5 mL of urine. Using the sterile aseptic technique, transfer the urine to a sterile container (see Chapter 32).

Time required between collections may be 2, 12, or 24 hours. The timed period begins after the patient urinates and ends with a final voiding at the end of the time period. The patient voids into a clean receptacle, and the urine is transferred to the special collection container, which may contain special preservatives. Each specimen must be free of feces and toilet tissue. Missed specimens make the entire collection inaccurate. Check agency policy and with the laboratory for specific instructions.

urine colour and will cause a false positive on a urinalysis. For example, phenazopyridine, a urinary analgesic, colours the urine bright orange. Eating beets, rhubarb, or blackberries may cause red urine. Special dyes used in intravenous diagnostic studies also discolour urine. Dark amber urine may result from high concentrations of bilirubin caused by liver dysfunction or vitamin B. Document and report any abnormal colour or sediment, especially if the cause is unknown.

Clarity. Normal urine appears transparent at voiding. Urine that stands for several minutes in a container becomes cloudy. Freshly voided urine in patients with renal disease may appear cloudy or foamy because of high protein concentrations. Urine also will appear thick and cloudy as a result of bacteria.

Odour. Urine has a characteristic odour. The more concentrated the urine, the stronger the odour. Stagnant urine has an ammonia odour, which is common in patients who are repeatedly incontinent. A sweet or fruity odour occurs from acetone or acetoacetic acid (by-products of incomplete fat metabolism) seen with diabetes mellitus or starvation.

Urine Testing. It is common to collect urine specimens for laboratory testing (Table 43-2). The type of test being done determines the method of collection. All specimens are labelled with the patient's name, the date, and the time of collection. Specimens should be transported to the laboratory quickly to ensure accuracy of test results. Agency infection control policies require adherence to standard precautions or routine practices by all personnel during the handling of specimens (see Chapter 32).

Specimen Collection. You will collect random, clean-voided or midstream (Skill 43-1), sterile (Figure 43-9), and timed specimens.

Urine Collection in Children. Collecting specimens from infants and children is often difficult. School-aged children and adolescents are usually able to cooperate, although they may be embarrassed. Preschool children and toddlers have difficulty voiding on request. Offering a young child fluids 30

Figure 43-9 Urine specimen collection: aspiration from a collection port in drainage tubing on an in-dwelling catheter.

minutes before requesting a specimen may help. You must use terms for urination that the child can understand. A young child may be reluctant to void in unfamiliar receptacles. A potty-chair or specimen hat placed under the toilet seat is usually effective. You must use special collection devices for infants and toddlers who are not toilet trained. Clear plastic, single-use bags with self-adhering material can be attached over the child's urethral meatus. Specimens should not be obtained by squeezing urine from the diaper material because test results may be inaccurate.

Common Urine Tests

Urinalysis. The laboratory performs a **urinalysis** on a specimen obtained through any of the previously described methods. Table 43-3 lists normal values for a urinalysis. The specimen should be examined as soon as possible after it is collected, preferably within two hours. It should be the first voided specimen in the morning to ensure a uniform concentration of constituents. For a quick screening, you can perform

► SKILL 43-1 Collecting a Midstream (Clean-Voided) Urine Specimen

Delegation Considerations

Collecting a midstream (clean-voided) urine specimen may be delegated to unregulated care providers (UCPs). If appropriate, an alert patient who is physically able may be instructed to collect the specimen. It is your responsibility to ensure that this specimen is obtained correctly and in a timely manner. Be aware of agency policy regarding specimen collection.

Instruct the UCP to inform you of the following:

- When the specimen was obtained
- Whether the patient was unable to initiate a stream or had pain or burning on urination
- Whether the collected specimen is dark, bloody, or cloudy; is odorous; or contains mucus

Equipment

- Soap or cleansing solution, washcloth, towel, and handwashing basin
- Commercial kit for clean-voided specimen or individual supplies as listed
- Sterile cotton balls or sterile gauze pads
- Antiseptic solution (e.g., chlorhexidine or povidone-iodine); check for patient allergy, and if allergy exists, provide an alternative
- Sterile water
- Sterile specimen collection cup or jar
- Sterile and nonsterile (disposable) gloves
- Bedpan, bedside commode, or specimen hat
- Completed specimen label
- Completed laboratory requisition form

Procedure

STEPS

1. Assess voiding status of patient:
 - A. When patient last voided
 - B. Level of awareness or developmental stage
 - C. Mobility, balance, and physical limitations
2. Assess patient's understanding of purpose of test and method of collection.
3. Explain procedure to patient:
 - A. Reason midstream specimen is needed
 - B. Ways patient and family can assist
 - C. Ways to obtain specimen free of feces
4. Provide fluids to drink a half-hour before collection unless contraindicated (i.e., fluid restriction) if patient does not feel urge to void.
5. Identify patient and perform hand hygiene.
6. Provide privacy for patient by closing door or bed curtain.
7. Give patient or family members soap, washcloth, and towel to cleanse perineal area.
8. Apply nonsterile gloves and assist nonambulatory patients with perineal care. Assist female patient onto bedpan. Raise head of bed.
9. Using surgical asepsis, open sterile kit (see Step 9 illustration) or prepare sterile supplies. Apply sterile gloves after opening sterile cup, placing cap with sterile inside surface up; do not touch inside of container or cap (see Chapter 32).

Step 9 Commercial midstream urine collection kit.

RATIONALE

- May indicate readiness to void.
- Reveals patient's ability to cooperate during procedure.
- Determines level of assistance in acquiring specimen.
- Information allows for clarification and promotes patient cooperation.
- Helps patient understand the procedure.
- Feces change characteristics of urine and may cause abnormal values.
- Improves likelihood of patient being able to void.
- Ensures accuracy of specimen collection. Decreases likelihood of transfer of microorganisms.
- Privacy allows patient to relax and produce specimen more quickly.
- Patient may prefer to wash own perineal area. Cleansing prevents contamination of specimen as urine passes from urethra.
- Provides easy access to perineal area to collect specimen. Semisitting position may ease voiding.
- The sterile technique is essential to maintain sterility of equipment and specimen. Sterile gloves prevent the transmission of microspecimen. A contaminated specimen is the most frequent reason for inaccurate reporting of urine cultures and sensitivities.

10. Pour antiseptic solution over cotton balls or gauze pads unless kit contains prepared gauze pads in antiseptic solution.

- Cotton balls or gauze pads will be used to further cleanse the perineum.

Continued

► SKILL 43-1 Collecting a Midstream (Clean-Voided) Urine Specimen—cont'd

11. Assist or allow patient to independently cleanse perineum and collect specimen:

A. Female patient

- (1) Spread labia with thumb and forefinger of nondominant hand.
- (2) Cleanse area with cotton ball or gauze, moving from front (above urethral orifice) to back (toward anus; see Step 11A(2) illustration). Using a fresh swab each time, repeat front to back motion three times (begin left side, then right side, then centre).
- (3) If agency policy indicates, rinse area with sterile water, and dry with cotton ball or gauze.
- (4) While you continue holding patient's labia apart, patient should initiate stream; after stream is achieved, pass container into stream and collect 30 to 60 mL (see Step 11A(4) illustration).

- Provides access to urethral meatus.
- Cleanse from area of least contamination to area of greatest contamination to decrease bacterial levels.
- Prevents contamination of specimen with antiseptic solution.
- Initial stream flushes out microorganisms that accumulate at the urethral meatus and prevents transfer into specimen.

Step 11A(2) Cleansing technique (female).

Step 11A(4) Specimen collection (female).

B. Male patient

- (1) Hold patient's penis with one hand; using circular motion and antiseptic swab, cleanse end of penis, moving from centre to outside (see Step 11B[1] illustration). In uncircumcised men, the foreskin should be retracted before cleansing.
- (2) If agency procedure indicates, rinse area with sterile water, and dry with cotton ball or gauze.
- (3) After patient has initiated urine stream, pass specimen collection container into stream and collect 30 to 60 mL (see Step 11B[3] illustration).

- Cleanse from area of least contamination to area of greatest contamination to decrease bacterial levels.
- Prevents contamination of specimen with antiseptic solution.
- Initial stream flushes out microorganisms that accumulate at the urethral meatus and prevents transfer into specimen.

Step 11B(1) Cleansing technique (male).

Step 11B(3) Specimen collection (male).

► SKILL 43-1 Collecting a Midstream (Clean-Voided) Urine Specimen—cont'd

12. Remove specimen container before flow of urine stops and before releasing labia or penis. Patient finishes voiding in bedpan or toilet. If foreskin was retracted for specimen collection, it must be replaced over the glans.
 13. Replace cap securely on specimen container (touch outside only).
 14. Cleanse any urine from exterior surface of container, and place in a plastic specimen bag.
 15. Remove bedpan (if applicable), assist patient to comfortable position, and provide handwashing basin if needed.
 16. Label specimen, and attach laboratory requisition.
- Prevents contamination of specimen with skin flora. If foreskin is not replaced, swelling and constriction may occur, causing pain and possible obstruction of urine flow.
 - Retains sterility of inside of container and prevents spillage of urine.
 - Prevents transfer of microorganisms to others.
 - Promotes relaxing environment.
 - Prevents inaccurate identification that could lead to errors in diagnosis or treatment.

Critical Decision Point: If patient is menstruating, indicate this information on the laboratory requisition.

17. Remove gloves, dispose of them in proper receptacle, and perform hand hygiene.
 18. Transport specimen to laboratory within 15 to 30 minutes or refrigerate immediately.
- Reduces transmission of infection.
 - Because bacteria grow quickly in urine, urine not received by the laboratory within 30 minutes should be refrigerated. However, refrigeration should not exceed two hours (Pagana & Pagana, 2007).

Unexpected Outcomes

Urine specimen is contaminated with feces or toilet paper

Specimen is accidentally discarded

Related Interventions

- Repeat instruction to patient or assist patient in obtaining a new specimen.
- Obtain a new specimen.
- Consider using a straight catheterization to obtain specimen.
- Repeat specimen collection.

Recording and Reporting

- Record date and time urine specimen was obtained in nurses' notes.
- Notify physician or nurse practitioner of any significant abnormalities.

Home Care Considerations

- If patient is required to collect specimen as an outpatient, a clean technique may be used. Provide proper instruction for collection.
- Appropriate equipment must be given to the patient and family.
- Information on storing the specimen until time of delivery to doctor's office or hospital laboratory must be provided.

certain portions of the urinalysis with special reagent strips. Dip the strip into the urine and observe for a colour change in the time interval designated on the package (Figure 43-10).

Specific Gravity. The **specific gravity** is the weight or degree of concentration of a substance compared with an equal amount of water. A urine specimen is poured into a special dry, clean cylinder. The weighted urinometer is suspended in the cylinder of urine. The concentration of dissolved substances in the urine aids in the determination of a patient's fluid balance. This measurement is always done as part of a complete urinalysis. If you are working in a critical care unit, you may be responsible for doing periodic measurement of specific gravity of urine as part of a complete assessment of specific patients.

If questions regarding the accuracy of specific gravity measurements arise, a urine osmolality test should be obtained. Although both tests measure urine concentration, the osmolality test is more accurate because it measures the total number of particles in a solution (see Chapter 39).

Urine Culture. For a urine culture, a sterile or clean-voided sample of urine is required. Early-morning specimens should be obtained when possible because bacterial counts are highest at that time (Fischbach, 2008). Because urine is an

excellent medium for bacterial growth and bacteriological changes may alter test results, facilities may require that urine samples for culture and sensitivity be stored in a refrigerator until pickup.

It will be approximately 24 to 48 hours before the laboratory can report findings of bacterial growth. While results are awaited, a broad-spectrum antibiotic may be ordered as soon as a culture has been obtained. The test for sensitivity determines which specific antibiotics are effective. The results of a urine culture may show that another antibiotic would be more effective. In this case, a new antibiotic is ordered.

Diagnostic Examinations

The urinary system is amenable to accurate diagnostic study by several radiographic techniques. The two approaches for visualization of urinary structures, direct and indirect techniques, can be quite simple or very complex, necessitating extensive nursing intervention. These procedures are further subdivided into invasive or noninvasive categories (Table 43-4). One noninvasive procedure involves computed tomography (CT), shown in Figure 43-11.

Many of the nursing responsibilities related to diagnostic examinations of the urinary tract are common to more than

▶ TABLE 43-3 Routine Urinalysis

**Measurement (Normal Value)****Routine Laboratory Value**

pH (4.6–8.0, average 6.0)

Protein (none or up to 8 mg/100 mL)

Glucose (none)

Ketones (none)

Blood (up to two red blood cells [RBCs])

Specific gravity (1.010–1.025)

Interpretation

pH indicates acid–base balance. Urine that stands for several hours becomes alkaline. An acid pH helps protect against bacterial growth.

Protein is not normally present in urine. It is seen in renal disease because damage to glomeruli or tubules allows protein to enter urine.

Diabetic patients have glucose in their urine as a result of inability of tubules to reabsorb high glucose concentrations (180 mg/100 mL). Ingestion of high concentrations of glucose may cause some glucose to appear in the urine of healthy people.

Patients whose diabetes mellitus is poorly controlled experience breakdown of fatty acids. Ketones are end products of fat metabolism. Patients with dehydration, starvation, or excessive aspirin usage also may have **ketonuria**.

Damage to glomeruli or tubules may allow RBCs to enter the urine. Trauma, disease, or surgery of the lower urinary tract also may cause blood to be present. In women, blood in a routine urine specimen may indicate contamination with menstrual fluid.

Specific gravity measures concentration of particles in urine. High specific gravity reflects concentrated urine, and low specific gravity reflects diluted urine. Dehydration, reduced renal blood flow, and increased antidiuretic hormone (ADH) secretion elevate specific gravity. Overhydration, early renal disease, and inadequate ADH secretion reduce specific gravity.

Microscopic Examination

White blood cells (WBCs) (0–4 per low-power field)

Bacteria (none)

Casts (none)

Greater numbers may indicate urinary tract infection (UTI).

Bacteria indicate UTI. (Patient may or may not have symptoms.)

Casts are cylindrical bodies whose shapes take on the likeness of objects within the renal tubule. Types include hyaline, WBCs, RBCs, granular cells, and epithelial cells. Their presence is always an abnormal finding and indicates renal alterations.

Data from Pagana, K. D., & Pagana, T. J. (2007). *Mosby's diagnostic and laboratory test reference* (8th ed.). St Louis, MO: Mosby.

Figure 43-10 Checking results of a chemical reagent strip dipped in urine.

Figure 43-11 Equipment for computed tomography. **Source:** From Brundage, D. J. (1992). *Renal disorders*. St Louis, MO: Mosby.

one type of procedure. Common responsibilities before an examination include the following:

- Witnessing a signed consent (if agency policy)
- Assessing the patient for history of shellfish (iodine) allergy, which predicts allergy to the dye used in specific studies (intravenous pyelogram [IVP] and renal arteriogram)
- Administering bowel-cleansing medications (check agency policy)
- Ensuring that the patient receives the appropriate pretest diet (clear liquids) or nothing by mouth (NPO), as needed

Common postprocedure interventions may include the following:

- Assessing intake and output
- Observing characteristics of urine (colour, clarity, presence of blood)

Patient Expectations

Patients depend on their caregivers to recognize and promptly meet their needs. Nurses need to use a skilled and caring approach, be creative in using a variety of assessment techniques, and serve as a patient advocate. A caring nurse will meet the patient's needs in a way that is acceptable and

► TABLE 43-4 Diagnostic Examinations

Name of Procedure	Purpose and Method of Procedure	Special Nursing Considerations
Noninvasive Procedures		
Abdominal roentgenogram(plain film; kidney, ureter, bladder [KUB], or flat plate)	To determine the size, shape, symmetry, and location of the kidneys; diagnose urinary calculi; preliminary X-ray imaging before intravenous pyelogram (IVP).	No special preparation or precautions; bowel preparation is required if preliminary X-ray imaging before IVP.
Computerized axial tomographic (CT) scan (see Figure 43-11)	A computerized X-ray procedure used to obtain detailed images of structures within a selected plane of the body. The computer reconstructs a cross-sectional image and thus allows the physician to view pathological conditions such as tumours and obstructions.	Bowel cleansing as per agency or physician preference. Assess patient for shellfish (iodine) allergy if a CT scan with contrast material is ordered. Prepare patient for the procedure (e.g., patient will be placed into a large machine and need to lie still, feelings of claustrophobia occur in some patients). Bowel cleansing will be completed as per agency or physician preference. Only clear liquids are permitted until after test is completed. Assess patient for shellfish (iodine) allergy before test. After test, fluid intake is encouraged to dilute and flush dye from patient. Observe for late symptoms of allergic reaction (rash, throat tightness, difficulty breathing, etc.). Same as for IVP.
Intravenous pyelogram (IVP)	To view the collecting ducts and renal pelvis and outline the ureters, bladder, and urethra with the use of dye, which is excreted through the urine. A special dye is injected intravenously. The patient's ability to empty the bladder is assessed through a postvoiding X-ray film.	Assess patient for shellfish (iodine) allergy before test. After test, fluid intake is encouraged to dilute and flush dye from patient. Observe for late symptoms of allergic reaction (rash, throat tightness, difficulty breathing, etc.). Same as for IVP.
Retrograde pyelogram	Series of X-ray films that provide detailed anatomical views of the ureter, ureteropelvic junction, renal pelvis, and calyces. A ureteral catheter is placed in the lower ureteral segment, and contrast material is injected or infused into the upper urinary tract.	Assess patient for shellfish (iodine) allergy before test.
Retrograde urethrogram (RUG)	To obtain oblique X-ray films of the male urethra by instilling a small volume of iodine-bound contrast material into the urethra from a retrograde direction.	Assess patient for shellfish (iodine) allergy before test.
Renal (kidney) scan	To determine renal blood flow, anatomical structure of the kidneys, and excretory function using a radioisotope.	Usually no bowel cleansing is needed, but check agency policy. After test, only precaution is rinsing bedpan or urinal after use and flushing the urine, as urine will contain a minute amount of radioisotope. Rinse fluid carefully using a double flush. No bowel cleansing is needed.
Renal ultrasonography	To identify gross renal structures and structural abnormalities in the kidney using high-frequency, inaudible sound waves.	No bowel cleansing is needed.
Bladder ultrasonography	To identify structural abnormalities of bladder or lower urinary tract. Also used to estimate the volume of urine in the bladder and to measure postvoid residual volume.	Patient may be asked to drink fluids before the ultrasonography to cause bladder distension for better results. To measure postvoid residual volume, ultrasonography should be performed within 15 minutes of void. No special care is necessary after either study.
Invasive Procedures		
Endoscopy	Use of an endoscope allows for direct visualization, specimen collection, or treatment of the interior of the kidney (nephroscopy), ureter (ureteroscopy), bladder (cystoscopy), and urethra (cystourethroscopy). Although this procedure may be accomplished using local anaesthesia, it is more commonly performed using general anaesthesia or conscious sedation to avoid unnecessary anxiety and trauma for the patient.	Signed consent is obtained. If ordered, a bowel cleansing is completed. Follow agency policy for preoperative preparation and checklist (see Chapter 48). After patient's return, assess the vital signs and the characteristics of urine, monitor intake and output, encourage ingestion of fluids, and observe for fever, dysuria, and pain in the suprapubic region.

Continued

► **TABLE 43-4** Diagnostic Examinations—cont'd

Name of Procedure	Purpose and Method of Procedure	Special Nursing Considerations
Arteriogram (angiography)	Used primarily to visualize the renal arteries or their branches to detect narrowing or occlusion. A catheter is placed in one of the femoral arteries and introduced up to the level of the renal arteries. Radiopaque contrast is injected through the catheter while X-ray images are taken in rapid succession.	Signed consent is required. Assess for shellfish (iodine) allergy. Follow agency preprocedure checklist. After the procedure, monitor vital signs frequently until stable; bed rest is maintained for prescribed time interval; fluids are encouraged to flush the contrast from the system. Also monitor the affected extremity for neurocirculatory function (pulse, skin temperature, sensation, and movement), and observe catheter site for bleeding, swelling, increased tenderness, or hematoma formation. Physician must be notified immediately of any postprocedure abnormality.
Urodynamic testing (cystometrogram)	Determines bladder and sphincter function in the case of urinary obstruction or urinary incontinence. A catheter is inserted, the urine is drained, and sterile water or contrast liquid is used to fill the bladder. Pressure readings are taken and compared with the patient's reported sensations.	Explain the need for the patient to report all sensations during the test. After the test, assess the patient for sensations of sweating, pain, nausea, bladder fullness, or a strong urge to void.

Adapted from Malarkey, L. M., & McMorrow, M. E. (2005). *Saunders' nursing guide to laboratory and diagnostic tests*. St Louis, MO: Saunders.

individualized to the patient and the family situation. Patients with alterations in urinary elimination expect you to be respectful of privacy needs and sensitive to the impact of urinary impairments on sexuality and self-concept. You and your patient should develop the care plan together whenever possible and establish goals that are mutually acceptable. Cultural practices and personal preferences also must be considered.

❖ Nursing Diagnosis

A thorough assessment of the patient's urinary elimination function reveals patterns of data that allow you to make relevant and accurate nursing diagnoses. The diagnosis may focus on a specific alteration or an associated problem such as impaired skin integrity related to urinary incontinence. Identification of defining characteristics leads you to select an appropriate diagnosis. Specifying related factors for each diagnosis allows selection of individualized nursing interventions (see Chapter 13). A sample of diagnostic reasoning is found in Box 43-3. Nursing diagnoses common to patients with alterations in urine elimination include the following:

- *Disturbed body image*
- *Pain (acute, chronic)*
- *Self-care deficit, toileting*
- *Impaired skin integrity*
- *Impaired urinary elimination*
- *Urinary incontinence (transient, urge, stress, mixed, functional, overflow, reflex, total)*
- *Urinary retention*

Common symptoms that contribute to a nursing diagnosis of impaired urinary elimination, such as frequency, urgency, and nocturia, were described in Table 43-1. Each of these symptoms is associated with multiple underlying disorders. You assimilate what has been learned from personal history taking, physical assessment, and diagnostic tests to determine a nursing diagnosis and an appropriate care plan.

► BOX 43-3 NURSING DIAGNOSTIC PROCESS

Assessment Activities	Defining Characteristics	Nursing Diagnosis
Have patient describe situations that accompany urine leakage.	Patient states that she "loses a little urine" whenever she sneezes, coughs, or laughs. Patient states that she has been having problems for several years.	<i>Stress urinary incontinence related to decreased pelvic muscle tone and urethral sphincter trauma</i>
Observe patient behaviour.	Patient is wearing a menstrual minipad continuously. Patient is reluctant to interact with others and tries not to cough or laugh.	
Review medical history.	Patient is menopausal after three vaginal births.	

❖ Planning

During planning, you need to integrate the knowledge gained from assessment and the knowledge related to resources and available therapies to develop an individualized care plan (Box 43-4). The patient's needs should be matched with clinical and professional standards recommended in the literature (Figure 43-12). Building a relationship of trust with the patient

Figure 43-12 Critical thinking model for urinary elimination planning.

is important because implementing the care plan involves interaction of a very personal nature.

Goals and Outcomes

The care plan for alterations in urinary elimination must include realistic and individualized goals along with relevant outcomes. You and your patient must collaborate in setting goals and outcomes. A general goal might be normal urinary elimination, but the individual goal may differ depending on the problem. The goals may be short term or long term. For example, for a patient with urinary retention after surgery, the short-term goal may be "Patient will have normal voiding with complete bladder emptying within 24 hours." Relevant expected outcomes for this goal may include the following:

- Patient will void within eight hours.
- Urinary output of 300 mL or greater will occur with each voiding.
- Patient's bladder will not be distended on palpation.
- Patient will not continually feel an urge to void.

Conversely, the patient with stress incontinence may have a long-term goal that involves weeks of pelvic floor muscle exercise (PFMEs; also known as Kegel exercises) to achieve urinary control: "Patient will achieve improved urinary continence within 12 weeks after start of exercise program (Kegel)." Goals must be reasonably achievable for the patient and be relevant to the patient's situation.

Setting Priorities

Urinary elimination is a personal and intimate activity. You must establish a relationship with the patient that promotes open discussion. A supportive and collaborative environment allows the patient's priorities to become apparent and fosters mutual understanding of realistic goals.

When a patient has multiple nursing diagnoses (Figure 43-13), you must recognize the primary health problem and its influence on other problems. In the example of the patient with chronic confusion, the resultant incontinence creates several risks. Focusing on management of incontinence will often help to resolve more than one nursing diagnosis. Although physical care needs may appear to have higher priority, psychological needs related to self-esteem or sexuality may be of higher priority to the patient. Attention to the patient's

BOX 43-4 NURSING CARE PLAN

Mixed Urinary Incontinence

Assessment

Kay, a home care nurse, is seeing Mrs. Grayson, a 75-year-old widow, at her home. Mrs. Grayson was referred by her physician because of arthritis. She lives alone, but her daughter lives less than a 10-minute drive away. Kay's assessment included a discussion of Mrs. Grayson's current health problems.

Assessment Activities

Ask Mrs. Grayson about how she is coping with her arthritis.

Findings and Defining Characteristics

She responds, "It slows me down. The pain medication is helping, but it takes me longer to get out of my chair and get anywhere." Mrs. Grayson begins to cry and states, "You can see the plastic cover on my chair. I'm so embarrassed; sometimes I can't get out of the chair fast enough and I lose my water. I've been wearing those diapers lately."

Continued

► BOX 43-4 NURSING CARE PLAN—cont'd

Assessment Activities

Ask Mrs. Grayson to describe how long she has had trouble controlling her urine and whether she has ever sought help.

Ask Mrs. Grayson about any changes, such as new medication, that may have contributed to her worsening symptoms.

Ask Mrs. Grayson to complete a bladder diary for three days when she is likely to be at home most of the time, and provide a receptacle so that she can measure several of her voids. Establish diary format she understands and can work with.

Assess bladder diary findings and discuss patterns with Mrs. Grayson so she becomes aware of her usual bladder routines and is more able to participate in her care planning.

Findings and Defining Characteristics

Mrs. Grayson says that she has had trouble with dribbling for more than 10 years, but she really didn't think anything could be done about it because of her age. Over the past few years, it has gotten worse. With little warning, she has to rush to the bathroom and is often wet on the way.

Mrs. Grayson says that she has not started any new medications.

Mrs. Grayson completes the diary for only two days because she finds it difficult to write everything down.

The diary findings discussed are as follows:

1. Largest volume void is 200 mL and longest interval between voids is 1.25 hours. Mrs. Grayson is up three to four times at night to void.
2. Two episodes of incontinence occur on the way to the bathroom. Mrs. Grayson records that she gets a sudden urge to void but is "very wet" on the way to the bathroom.
3. Mrs. Grayson also records that she can feel herself dribbling while coughing.
4. Fluid intake is low, averaging 800 mL per 24 hours.

Nursing Diagnosis: *Mixed incontinence.* Mrs. Grayson has symptoms of urge incontinence: frequency, incontinence associated with severe urgency, and nocturia. She also describes episodes of stress incontinence. Her impaired mobility makes it more difficult to get to the bathroom in time. Mrs. Grayson also may be at risk for a urinary tract infection (UTI) due to reduced fluid intake.

Planning

Goals (Nursing Outcomes Classification)*

Patient will review bladder diary and think about aspects of her elimination pattern that may be amenable to change.

Patient will report reduced episodes of incontinence within one month and longer intervals between voids.

Patient will increase fluid intake to help ensure adequate hydration and prevent urinary tract infection.

Expected Outcomes

Enhanced understanding of bladder function

Reduced episodes of urinary incontinence

Adequate hydration

*Outcome classification labels from Moorhead, S., Johnson, M., Maas, M. L., & Swanson, E. (Eds.). (2008). *Nursing outcomes classification (NOC)* (4th ed.). St Louis, MO: Mosby.

Interventions (Nursing Interventions Classification)

Urinary Incontinence Care

Discuss "normal" bladder habits with patient as well as her actual patterns of intake and output, based on bladder diary.

Assess patient's pelvic floor strength digitally to establish baseline and to teach patient appropriate muscle to tighten. Instruct patient to practise PFMEs at least twice a day (see Box 43-12).

Work with patient to establish a manageable program of bladder training, asking the patient to void at regular, prespecified intervals throughout the day based on maximum intervals in bladder diary (1.25 hours). Gradually increase the interval by 15 to 30 minutes per week as tolerated, until acceptable pattern is achieved.

Rationale

The success of conservative therapies for urinary incontinence (UI) such as pelvic floor muscle exercises (PFMEs) requires motivation and ongoing commitment and self-care, meaning that the patient must be an active part of assessment and care planning.

Cognitively intact and motivated older adults can learn PFMEs when able to identify the correct musculature. Growing evidence supports the positive impact of PFMEs in women with stress UI and overactive bladder syndrome (OAB), including the reflex inhibition of involuntary detrusor contractions (Hay-Smith & Dumoulin, 2007).

Bladder training reduces frequency and urgency in women with OAB (Milne, 2008) but may be more successful when pelvic floor muscle strength has improved.

BOX 43-4 NURSING CARE PLAN—cont'd

Interventions (Nursing Interventions Classification)

Discuss safety issues related to the patient's nocturia and the possibility of acquiring a bedside commode.

Encourage patient to increase noncaffeinated fluid intake gradually to approximately 1500 mL, with fluid intake restricted to two hours before bedtime.

Rationale

Older adults who get up at night to urinate are more likely to experience a fall. Because older adults are also at increased risk for bone fractures, it is important to identify those with nocturia and to ensure that appropriate safety precautions are taken.

Adequate hydration will help prevent urinary tract infection (UTI) and maintain dilute urine. Avoiding fluids before bedtime may reduce nocturia.

Evaluation

Nursing Action

Ask Mrs. Grayson to complete a bladder diary at regular intervals (monthly or every two months) to compare to the baseline diary.

Patient Response and Finding

Three months after initiating conservative treatment, patient responds, "I'm dry most of the time now."

Achievement of Outcome

Mrs. Grayson has reduced her episodes of incontinence and increased the interval between voids. She is now voiding every three hours on average and is up one or two times at night. She reports that she feels better because she is getting more sleep.

Figure 43-13 Concept map for patient with urinary tract infection (UTI) and dementia. CBC, Complete blood cell count; WBC, white blood cells.

perceived needs may be the most satisfactory and successful approach to accomplishing all of the goals. Reinforcement and praise of good health habits improve compliance with the care plan.

Continuity of Care

The care plan incorporates health promotion activities and therapeutic interventions for patients. Preventive interventions may be required for patients at risk for urinary problems. It is important to consider the patient's home environment and normal elimination routines when planning therapies. Consultation with other health care providers and with the patient's

family is often necessary. For example, the physiotherapist can design an exercise plan to increase strength and endurance so that the patient will be able to ambulate to the bathroom. The need for home care services should be explored and appropriate referrals made. The family may need to alter the home environment to make it easier and safer for the patient to use the bathroom.

Implementation

Implementation is the action phase of the nursing process. You will carry out the independent and collaborative activities

needed to assist the patient in achieving the desired outcomes and goals. Independent activities are those in which nurses use their own judgement. An example of these is teaching self-care activities to the patient. Collaborative activities are those prescribed by the physician that you carry out, such as medication administration.

Health Promotion

The focus of health promotion is to assist the patient in understanding and participating in self-care practices that will preserve and protect healthy urinary system function (Box 43-5). This can be achieved through several means.

Patient Education. Success of therapies aimed at solving or minimizing urinary elimination problems depends in part on successful patient education. Although many patients may need to learn about all aspects of urinary elimination, you should first focus the teaching on the patient's specific elimination problems. For example, patients who practise poor hygiene benefit most from learning about the normal sterility of the urinary tract and ways to prevent infection. Patients also learn the significance of symptoms of urinary alterations so that early preventive health care can be initiated.

BOX 43-5

FOCUS ON PRIMARY HEALTH CARE

Urinary Incontinence

People with urinary incontinence often attempt to manage the condition on their own and do not seek professional help because they are embarrassed, they believe that incontinence is a normal part of aging, or they are not aware of the treatment options. Consequently, routine screening for incontinence at the primary health care level should be the first level of assessment in provision of continence services. Such routine screening demonstrates that it is acceptable to discuss elimination problems and provides a forum for teaching about bladder health. Health promotion topics that should be taught include the following:

- Basic education about lower urinary tract function
- Education about promoting good bladder and bowel habits
- Education about risk factors, including smoking, caffeine, weight gain, and fluid restriction
- Education about preventing UTIs
- Providing information on resources

For patients already experiencing urinary incontinence, nurses at the primary health care level provide information about common causes, goals and expectations of treatment, and absorbent products available. You should communicate with other health care providers (particularly the patient's primary care provider) and be aware of how to access additional care at the secondary or tertiary levels. You should also be able to perform a focused assessment that includes obtaining relevant medical and surgical history, a focused physical examination, urinalysis by dipstick, and completion of a 24- to 72-hour bladder diary. You would then initiate behavioural interventions that are relevant to the nursing diagnosis

Sources: Adapted from Canadian Continence Foundation. (2001). *Promoting a collaborative consumer-focused approach to continence care in Canada*. Peterborough, ON: Author. Retrieved from <http://www.continence-fdn.ca>; and Gettliffe, K., & Thomas, S. (2007). Incontinence in perspective. In K. Gettliffe & M. Dolman (Eds.) *Promoting continence: A clinical and research resource* (3rd ed., pp. 1–23). Edinburgh: Bailliere-Tindall/Elsevier.

Nurses can easily incorporate teaching while providing nursing care. For example, when attempting to increase the patient's fluid intake, a good time to discuss the benefits of this action is while giving fluids with medications or meals. Teaching about perineal hygiene may be appropriate while giving a bath or performing catheter care.

Promoting Regular Micturition. Maintaining regular patterns of urinary elimination can help prevent many urination problems. Patients with urinary incontinence commonly void frequently throughout the day to avoid accidental urine loss. However, frequent voiding (e.g., at hourly intervals) may contribute to small-capacity bladders. Conversely, patients who hold their urine for long periods (more than eight hours) may develop a hypotonic bladder with incomplete emptying. You should reinforce the importance of voiding regularly (approximately every three to four hours) to help maintain a normal bladder capacity (400 to 500 mL). Because constipated stool in the rectum may compress the urethra and impede emptying, you should emphasize the importance of regular bowel movements and encourage measures to enhance regularity, including diets rich in fibre (see Chapter 44).

Many nursing measures have been designed to promote normal voiding in patients at risk for urination difficulties and in patients with established urination problems. You can initiate many of these measures independently.

Stimulating Micturition Reflex. The patient's ability to void depends on feeling the urge to urinate, being able to control the urethral sphincter, and being able to relax during voiding. You can help a patient learn to relax and stimulate the micturition reflex by enabling the patient to assume the normal position for voiding. A woman is better able to void in a squatting or sitting position. If the woman is unable to use toilet facilities, you can help her into a sitting position on a bedpan or bedside commode. A man voids more easily in a standing position. If the man cannot reach toilet facilities, he may stand at the bedside and void into a urinal (a metal or plastic receptacle for urine; Figure 43-14). At times, it may be necessary for one or more nurses to assist a man in standing.

Providing certain sensory stimuli also may promote relaxation and voiding. The sound of running water helps many patients void. Stroking the inner thigh may stimulate sensory nerves and promote the micturition reflex. You can also pour warm water over the patient's perineum to create the urge to urinate. If urine output is being measured, you must first measure the volume of water that will be poured over the perineal area.

Figure 43-14 Types of male urinals.

Maintaining Elimination Habits. Many patients follow routines to promote normal voiding. In a hospital or long-term care facility, nursing routines may conflict with those of patients. Integrating patients' habits into the care plan fosters normal voiding and will assist in preventing problems related to urination (Box 43-6).

Maintaining Adequate Fluid Intake. Patients with urinary incontinence often reduce fluid intake because they

believe that this will help keep them dry. In reality, maintaining an adequate fluid intake of 1500 to 2000 mL promotes continence because concentrated urine can irritate the bladder mucosa. Fluid intake should not include caffeinated beverages, which have a diuretic effect. Remind the patient that many vegetables and fruits have a high fluid content and can contribute to daily fluid intake. At the patient's home, it may be helpful to establish a schedule for drinking fluids (e.g., with meals or medications). Fluids should be avoided two hours before bedtime to minimize nocturia.

Avoiding Food and Fluids That Can Irritate the Bladder Mucosa. Teach the patient to avoid foods and fluids that may cause symptoms of urgency and frequency, including the following:

- Tobacco
- Alcohol
- Substances containing caffeine, such as coffee, tea, and chocolate
- Carbonated beverages
- Aspartame (artificial sweetener)
- Citrus fruits or juices
- Tomatoes or tomato-based products
- Greasy or spicy foods (Nygaard et al., 2008)

Promoting Complete Bladder Emptying. Under normal circumstances, a small amount of urine (50 mL) remains in the bladder after voiding (residual urine) because the urinary sphincters close. Thus, people normally remain continent and dry. People with residual urine are able to remain dry when their urethral closure pressure is sufficient to prevent leakage. However, urinary incontinence may occur when too much residual urine is in the bladder or when the urinary sphincters are too weak to maintain closure pressure. As well as contributing to incontinence, residual urine can be a medium for bacterial growth.

Patients should be encouraged to take their time while voiding and to try again when they feel they have not emptied their bladders fully. Those with consistently elevated postvoid residual volumes (>100 mL) may require intermittent catheterization. Portable bladder scanners offer a noninvasive means of assessing postvoid residual volumes.

Preventing Infection. One of the most important considerations for a patient with alterations in urinary elimination is the need to prevent infection of the urinary system. Good perineal hygiene that includes cleaning the urethral meatus after each voiding or bowel movement is essential. Patients with limited dexterity due to conditions such as arthritis or stroke can benefit from the use of a squirt bottle filled with warm water to rinse the perineum after defecation.

Maintaining an adequate daily intake of fluids (1500 to 2000 mL) dilutes urine and promotes regular micturition. Dehydration can contribute to urinary incontinence as concentrated urine can irritate the bladder (Wyman et al., 2009). Urine is normally acidic and tends to inhibit growth of microorganisms. Cranberry juice has been shown to lower urine pH and decrease bacterial adherence to the bladder wall (Jepson & Craig, 2008) and may be helpful in prevention of recurrent urinary tract infection in young to middle-aged women, but it has not been shown to be effective in children or people with in-dwelling catheters.

Acute Care

Many measures can be used in the acute care setting to decrease the incidence of urinary alterations. Box 43-7 lists

BOX 43-6 NURSING STORY

Motivated to Promote Continence

It is impossible to know how the seemingly isolated decisions we make now will continue to affect us. I had recently started working as a registered nurse in long-term care when the opportunity arose to enter the world of research. The proposed project would involve the assessment and treatment of 50 older adults with urinary incontinence. I knew as little about research as I did about incontinence, but my eyes were quickly opened. Interested residents and families lined the length of the hallway to attend the project's information session. What still stands out to me today is the fact that not one resident I spoke with that night had known before arriving at the facility that his or her urinary incontinence could be treated. The phrase "suffering in silence" had never been more true.

Assessment included much of what you are now familiar with—completing a bladder diary (by the resident or by a clinician as necessary), focused history, conducting blood work—and obtaining postvoid residual treatment was generally noninvasive: only one woman underwent surgery. The other participants initiated dietary modifications, bladder training, pelvic floor muscle exercises, or medication, or a combination of these. A regimen of prompted voiding was undertaken with residents who were cognitively impaired.

When assessment, intervention, and follow-up were complete approximately one year later, few of the 50 study participants were totally continent (i.e., dry). The majority, however, had at least 50% fewer episodes of incontinence. Of equal importance, these men and women understood that they were not alone and did not have to accept their incontinence as part of the aging process.

The differences that I witnessed in the participants' quality of life continue to motivate me in my work to this day. One resident who voided large volumes of urine each time she stood up, and who slept in her chair because she was afraid of soaking her bed, was able to leave the nursing home for the first time in years to visit with her brother before he died. Her treatment involved changing the medication that had contributed to her condition and ensuring that she had assistance to reach the toilet at appropriate times, as dictated by findings in her bladder diary.

On the down side, many of the participants' lifestyle improvements were not permanent. For a variety of reasons that included staffing shortages, supportive strategies such as prompted voiding and scheduled toileting were not well maintained after the project was completed, and several residents who required toileting assistance regressed despite earlier success. As a result of my participation, I was left with determination to teach those with urinary incontinence how to help themselves, and to teach caregivers that despite heavy workloads it is their ongoing responsibility to ask patients about urinary leakage, to direct them to the appropriate resources, and, above all, to ensure the dignity of those who are unable to help themselves by offering toileting assistance.

Author: Kathleen Hunter

► BOX 43-7

Urinary Incontinence Treatment Options

For Transient Incontinence

- Address underlying cause of incontinence (e.g., treat for infection or manage for constipation, as necessary)

For Urge Incontinence and Overactive Bladder

- Anticholinergic medications
- Bladder training
- Scheduled toileting
- Pelvic floor muscle exercises
- Biofeedback
- Lifestyle modifications (e.g., selected dietary and fluid modifications)

For Stress Incontinence

- Biofeedback
- Lifestyle modifications (e.g., weight loss, smoking cessation)
- Pessary
- Medications (i.e., estrogen replacement)
- Surgery
- Artificial sphincter

For Mixed Incontinence

- Interventions as for stress incontinence and urge incontinence

For Functional Incontinence

- Habit retraining
- Environmental alterations
- Scheduled toileting
- Condom catheter (men)
- Protective undergarments

For Overflow Incontinence

- Intermittent catheterization
- Surgery (i.e., for treatment of obstruction)
- Pessary for cystocele-related obstruction
- In-dwelling or condom catheter

For Reflex Incontinence

- Anticholinergic medications
- Surgery
- Intermittent catheterization
- In-dwelling or condom catheter

For Total Incontinence

- Artificial sphincter
- Surgery (e.g., sling procedure)
- Urinary diversion

some of the many types of interventions available for urinary incontinence.

Maintaining Elimination Habits. Patients usually require time to void. Requesting a urine specimen on demand does not contribute to relaxation and normal voiding habits. Patients should be given at least 30 minutes to provide a specimen. Patients normally void upon awakening or before meals; therefore, you should offer them the opportunity to use toilet facilities then. Also important is the need to respond promptly to patients' urges to urinate. Delays in assisting patients to the bathroom may interfere with normal micturition and contribute to incontinence. This is particularly the case with patients who have overactive bladders.

safety alert Many falls by older adults are related to the urge to urinate. Anticipate an older adult's need to urinate and provide scheduled bathroom visits. Make sure that the pathway between the bed and the toilet facility is clear of any barriers.

Privacy is essential to normal voiding. If the patient cannot reach the bathroom, make sure that the bedside curtain is closed. The debilitated patient at home may prefer to use a bedside commode screened by a partition or room divider. Young children are often unable to void in the presence of people other than their parents.

When possible, you should encourage the continued use of special measures that the patient uses to void. The patient may be able to relax and void more easily while reading or listening to music. Having a cup or glass of fluids also may promote urination.

Medications. Drug therapy, either alone or in combination with other therapies, can help problems of urinary incontinence and retention. The major categories of medication are presented in Table 43-5.

safety alert α -Adrenergic blockers may cause postural hypotension and increase the patient's risk of falling and injury. Instruct patients taking these medications to plan their nighttime toileting and to get out of bed slowly.

Catheterization. Catheterization of the bladder involves introducing a narrow tube through the urethra and into the bladder to allow a continuous flow of urine into a drainage receptacle. Indications for urethral catheterization are numerous in acute, community, and long-term care settings (Box 43-8). In acute care, catheterization is particularly useful for careful monitoring of output in hemodynamically unstable patients. Because bladder catheterization carries the risk of catheter-associated urinary tract infection (CAUTI), blockage, and trauma to the urethra, it is preferable to rely on other measures for either specimen collection or management of incontinence (Getliffe & Fader, 2007).

Types of Catheterization. Catheters may be intermittent or in-dwelling (retention). With the intermittent technique, a single-use straight catheter (Figure 43-15, A) is introduced for 5 to 10 minutes, just long enough to drain the bladder. The straight catheter has a single lumen with a small opening about 1.3 cm from the tip. Urine drains from the tip, through the lumen, and into a receptacle. Intermittent catheterization is performed by the patient or by a nurse and is common in patients who have incomplete bladder emptying due to neurogenic conditions (e.g., spinal cord injury). In hospital, intermittent catheterization is sterile to reduce the risk of nosocomial infections. In the community, patients use the clean intermittent catheterization technique and reuse their catheters many times. Catheters are washed with soap and water and left to air-dry until the next use. No evidence exists to confirm that UTIs are increased in people who use the clean technique rather than the sterile technique (Moore et al., 2007).

The coude catheter is a type of catheter that has a curved tip and is used for male patients who have enlarged prostates that partly obstruct the urethra. It is less traumatic during insertion because it is stiffer and easier to control than the straight-tip catheter.

An in-dwelling or Foley catheter (Figure 43-15, B) is retained for longer periods in the bladder by means of a small balloon that anchors it against the bladder neck. The catheter remains

► **TABLE 43-5** Medications Used to Treat Urinary Incontinence and Retention

Classification	Action	Generic Name	Side Effects	Contraindications Effects or Alerts/Comments
Urge incontinence: Anticholinergics or antimuscarinics	Anticholinergic/ antimuscarinic Inhibits effect of acetylcholine on smooth muscle antispasmodic	Oxybutynin Oxybutynin XL Tolterodine Tolterodine LA Fesoterodine Propiverine solifenacin	Constipation Dry mouth Blurred vision Confusion and decreased cognition in older adults Urinary retention	Narrow-angle glaucoma Gastrointestinal obstruction Ulcerative colitis Myasthenia gravis Retention elevated residual
Overflow incontinence from prostatic hyperplasia: α -Adrenergic blockers	Blocks α receptors to relax bladder neck or proximal urethra and reduce symptoms of obstructive voiding	Terazosin Doxazosin Tamsulosin	Postural hypotension Syncope fainting	Patients taking antihypertensives will require dosage titration
Overflow incontinence related to acute urinary retention: Cholinergic agents	Stimulates detrusor contraction	Bethanechol	May cause urethral resistance	Little effect in chronic urinary retention
Stress incontinence: α -Adrenergic agents	Stimulates α receptors at bladder neck or proximal urethra to increase tone and reduce stress incontinence	Pseudophedrine	Hypertension Insomnia Tremor Agitation	Monoamine oxidase inhibitors Hypertension Narrow-angle glaucoma Older patients
Stress or urge incontinence in women: Low-dose, topical hormone replacement therapy	Reduces irritation and atrophic vaginitis. Can reduce symptoms of overactive bladder and stress incontinence	Low-dose estrogen creams, tablets or rings	Sore breasts Spotting (rare with very low dose)	History of endometrial, ovarian, or breast cancer

► **BOX 43-8** Indications for Catheterization

Short-Term In-Dwelling Catheterization

- When urine outflow is obstructed (e.g., prostate enlargement)
- When bladder, urethra, and surrounding structures have been surgically repaired
- When seeking to prevent urethral obstruction from blood clots
- When measuring urinary output in critically ill patients
- When continuous or intermittent bladder irrigations are required

Long-Term In-Dwelling Catheterization

- When chronic urinary retention is not manageable by intermittent catheterization
- When skin rashes, ulcers, or wounds become irritated by contact with urine

- In those with a terminal illness when bed linen changes or toileting is painful

Intermittent Catheterization

- When seeking to relieve discomfort due to bladder distension, provision of decompression
- When required to obtain a sterile urine specimen
- When required to assess residual urine after urination
- When managing urethral strictures
- When engaging in the long-term management of patients with spinal cord injuries, neuromuscular degeneration, or incompetent bladders

in place until the patient is able to void completely and voluntarily or for as long as accurate measurements are needed. In-dwelling catheters are either two lumen (the most common type; one lumen drains urine and the other carries sterile water to inflate or deflate the balloon) or three lumen (the third lumen allows for irrigation). They can be used on a short-term or long-term basis.

Catheters are manufactured in many different materials (latex, silicone, Teflon) and come in many different diameters.

Guidelines on how to make appropriate decisions regarding catheter selection are provided in Box 43-9.

Catheter Insertion. For urethral catheterization of any type, a physician's order is required. You must use the strict aseptic technique (see Chapter 32). Organizing equipment before beginning the procedure prevents interruptions. The steps for inserting in-dwelling and single-use straight catheters are basically the same. The difference lies in the procedure taken to inflate the in-dwelling catheter balloon and secure the

Figure 43-15 Types of urinary catheters. **A**, Straight catheter. **B**, In-dwelling (Foley) catheter.

► BOX 43-9 Guidelines for Appropriate Catheter Selection

- The catheter size should be determined by the size of the patient's urethral canal. When the French system is used, the larger the gauge number, the larger the catheter size. In general, an 8 to 10 Fr gauge is required for children, and a 14 to 16 Fr gauge is required for adults (Gray et al., 2006). The smallest effective catheter size is preferred to prevent trauma.
- After urological procedures (prostatectomy), a 20 to 24 Fr three-lumen catheter is used to allow clot drainage and irrigation.
- The expected time required for catheterization will determine the catheter material selection (Teflon- or silicone-coated latex, 100% silicone, hydrophilic-coated latex).
- Plastic catheters are suitable only for intermittent use because of their inflexibility.
- Latex and rubber catheters are recommended for use up to three weeks. Be aware of patient allergies to either of these materials.
- Pure silicone or Teflon catheters are best suited for long-term use (two to three months) because they cause less encrustation at the urethral meatus.
- Silicone catheters have larger interior lumens than those of other catheters of the same size and may allow for more efficient urine drainage.
- Hydrophilic-coated catheters may be more comfortable and less likely to inflame urethral tissue than are nonhydrophilic catheters; encrustation may develop more slowly (Gray, 2006).
- For patients who develop encrustations and blockages frequently, the use of an inexpensive catheter changed every 7 to 10 days (depending on their pattern of blockage) may be more economical.
- For short-term use, silver-hydrogel catheters and catheters with anti-infective surfaces are effective in delaying the onset of bacteriuria.
- Balloon size is also important to consider when selecting an indwelling catheter. Balloon sizes range from 3 mL (pediatric) to large postoperative volumes (30 mL). In adults, the 5 mL size allows for optimal drainage, whereas the 30 mL size is used after prostatectomies to provide hemostasis of the prostatic bed (Gray et al., 2006).
- Only sterile water should be used to inflate the balloon because saline may crystallize, resulting in incomplete deflation of the balloon at the time of removal.
- Urine leakage around the catheter may be due to bladder spasms secondary to constipation or fecal impaction, the use of a large catheter balloon (30 mL), the use of a large catheter (>18 Fr), the presence of the UTI, kinking of the catheter, or trauma at the bladder neck from traction on the balloon. A change in lumen size, the use of anticholinergic medication, or a referral to a urologist may be warranted.

catheter. Skill 43-2 lists the steps for inserting in-dwelling and single-use straight catheters in both men and women.

Closed Drainage Systems. After inserting an in-dwelling catheter, maintain a closed urinary drainage system to minimize the risk of infection. Urinary drainage bags are plastic and can hold about 1000 to 1500 mL of urine. The drainage bag should never be raised above the level of the patient's bladder. The bag should hang on the bed frame or wheelchair without touching the floor. Urine in the bag and tubing can become a medium for bacteria, and infection is likely to develop if urine flows back into the bladder. Therefore, do not hang the bag on the bed's side rails because in that location it can be raised above the level of the bladder accidentally. When the patient ambulates, the drainage bag must be held below the patient's waist.

If the catheter must be disconnected from the drainage tubing, both tips should be cleansed with an alcohol swab

before being reconnected to minimize the transfer of microorganisms into the tubing.

Most drainage bags contain an antireflux valve to prevent urine in the bag from re-entering the drainage tubing and contaminating the patient's bladder. A spigot at the base of the bag is used to empty the bag. The spigot should always be clamped, except during emptying, and tucked into the protective pouch on the side of the bag (see agency policy). To ensure that the drainage system remains unobstructed, check for kinks or bends in the tubing, avoid positioning the patient on the drainage tubing, and observe for clots or sediment that may occlude the collecting tubing.

Routine Catheter Care. Patients with in-dwelling catheters have a number of special care needs. Nursing measures are directed at maintaining patient comfort, preventing infection, and maintaining an unobstructed flow of urine.

Text continued on p. 1146

► SKILL 43-2 Inserting a Straight or In-Dwelling Catheter

Delegation Considerations

Catheterization is usually not delegated to unregulated care providers (UCPs). However, in some settings, agency policy may permit this skill to be delegated to UCPs who have been properly instructed. UCPs routinely assist with positioning the patient and maintaining patient privacy and comfort, empty urine from the collection bag, and provide perineal care. If using an UCP, instruct him or her to inform you of the following:

- Patient discomfort or fever
- Abnormal colour, odour, or amount of urine in drainage bag

Equipment

Catheterization kit containing the following sterile items:

- Gloves (extra pair optional)
- Drapes, one fenestrated
- Lubricant
- Antiseptic cleansing solution
- Cotton balls
- Forceps
- Prefilled syringe with sterile water to inflate the balloon of an indwelling catheter
- Catheter of correct size and type for procedure (i.e., intermittent or in-dwelling)
- Sterile drainage tubing with collection bag and multipurpose tube holder or tape, safety pin, and elastic band for securing tubing to bed if patient is bed bound (for an in-dwelling catheter)
- Receptacle or basin (usually bottom of catheterization tray)
- Specimen container
- Blanket

Procedure

STEPS

1. Review patient's medical record, including physician's order and nurses' notes.
2. Close bedside curtain or door.
3. Assess status of patient:
 - A. Ask patient when he or she last voided, or check intake and output flow sheet, or palpate bladder.
 - B. Level of awareness or developmental stage
 - C. Mobility and physical limitations of patient
 - D. Patient's gender and age
 - E. Distended bladder
 - F. Perform hand hygiene. Apply clean gloves. Inspect perineum for erythema, drainage, and odour.
 - G. Note any pathological condition that may impair passage of catheter (e.g., enlarged prostate in men).
 - H. Allergies
4. Assess patient's knowledge of the purpose for catheterization.
5. Explain procedure to patient.
6. Arrange for extra nursing personnel to assist as necessary.
7. Perform hand hygiene.
8. Raise bed to appropriate working height.
9. Facing patient, stand on left side of bed if right-handed (on right side of bed if left-handed). Clear the bedside table and arrange equipment.
10. Raise side rail on opposite side of bed, and lower side rail on working side.
11. Place waterproof pad under patient.
12. Position patient:
 - A. Female patient

RATIONALE

- Determines purpose of inserting catheter: preparation for surgery, urinary irrigations, collection of sterile specimens, measurement of residual urine, and size and style of catheter. Assess for previous catheterization, including catheter size, response of patient, and time of last catheterization.
- Offers privacy, reduces embarrassment, and aids in relaxation during procedure.
- Determines time of last voiding or potential for bladder fullness.
- Reveals the patient's ability to cooperate and the level of explanation needed.
- Affects the way that the patient is positioned.
- Determines catheter size: 8 to 10 Fr is generally used for children, 14 to 16 Fr is indicated for adults, 12 Fr may be considered for young girls.
- Causes pain. Can indicate need to insert catheter if patient is unable to void independently.
- Reduces infection. Determines condition of the perineum.
- Obstruction prevents passage of catheter through urethra into the bladder. Use of coude catheter may be required.
- Procedure risks exposure to antiseptic, tape, latex, and lubricant. Betadine allergies are common; if the patient is unaware of allergy, ask if allergic to shellfish.
- Reveals need for patient instruction.
- Promotes cooperation.
- Patient may be unable to assume positioning for procedure.
- Reduces transmission of microorganisms.
- Promotes use of proper body mechanics.
- To insert catheter successfully, you must assume a comfortable position with all equipment easily accessible.
- Promotes patient safety.
- Prevents soiling of bed linens.

Continued

► SKILL 43-2 Inserting a Straight or In-Dwelling Catheter—cont'd

- (1) Assist to dorsal recumbent position (supine with knees flexed). Ask patient to relax thighs so that the hips can be rotated externally.
- (2) Assist to side-lying (Sims') position with upper leg flexed at hip if unable to assume dorsal recumbent position. If this position is used, you must take extra precautions to cover rectal area with drape to reduce chance of cross-contamination.

B. Male patient

- (1) Assist to supine position with thighs slightly abducted.

13. Drape patient:

A. Female patient (see Step 13A illustration)

- (1) Drape with bath blanket. Place blanket in diamond fashion over patient, with one corner at patient's midsection, side corners over each thigh and abdomen, and last corner over perineum.

B. Male patient (see Step 13B illustration)

- (1) Drape upper trunk with bath blanket and cover lower extremities with bedsheets, exposing only genitalia.

Step 13A Draping technique (female).

- Provides good visualization of perineal structures. Support legs with pillows to reduce muscle tension and promote comfort.
- This alternative position is used if patient cannot abduct legs at hip joint (e.g., if patient has arthritic joints). Support patient with pillows if necessary to maintain position.
- Comfortable position for patient that aids in visualization.
- Avoids unnecessary exposure of body parts and maintains patient's comfort.

Step 13B Draping technique (male).

14. Wearing disposable gloves, wash perineal area with soap and water as needed; dry thoroughly. Remove and discard gloves; perform hand hygiene.
15. Position lamp to illuminate perineal area (have an assistant hold flashlight, if necessary).
16. Open package containing drainage system; place drainage bag over edge of bottom bed frame, and bring drainage tube up between side rails and mattress.

- Reduces microorganisms near urethral meatus and allows further opportunity to visualize perineum and landmarks.
- Permits accurate identification and good visualization of urethral meatus.
- Prepares system for eventual connection with catheter.

Critical Decision Point: This step is necessary only when an in-dwelling catheter is being inserted and a drainage system is not part of the catheterization kit.

17. Open catheterization kit according to directions, keeping bottom of container sterile.

- Prevents transmission of microorganisms from table or work area to sterile supplies. The materials in the kit are arranged in sequence of use.

► SKILL 43-2 Inserting a Straight or In-Dwelling Catheter—cont'd

18. Place plastic bag that contained kit within reach of work area to use as a waterproof bag to dispose of used supplies.
19. Apply sterile gloves (see Chapter 32).

- Allows you to handle sterile supplies without contamination.

Critical Decision Point: If underpad is the first item in the catheterization kit, place pad plastic side down under patient, touching only the edges so as to maintain sterility. Then apply sterile gloves.

20. Organize supplies on sterile field. Open inner sterile package containing catheter. Pour sterile antiseptic solution into correct compartment containing sterile cotton balls. Open packet containing lubricant. Remove specimen container (lid should be placed loosely on top) and prefilled syringe from collection compartment of tray, and set them aside on sterile field.

- Maintains principles of surgical asepsis and organizes work area.
- Note: Pretesting of balloon is no longer recommended because catheters are pretested during manufacturing and inflation may distort the balloon, leading to increased trauma (Smith, 2006).

21. Lubricate 2.5 to 5 cm of catheter for women and 12.5 to 17.7 cm for men.

- Makes insertion of the catheter easier by decreasing friction.

Critical Decision Point: Some catheters have plastic sheaths over them that must be removed before lubrication. In some cases, the physician may order local anaesthetic lubricant.

22. Apply sterile drape:

A. Female patient

- (1) Allow top edge of drape to form a cuff over both gloved hands. Place drape on bed between patient's thighs. Slip cuffed edge just under buttocks, taking care not to touch contaminated surface with gloves.
- (2) Pick up fenestrated sterile drape and allow it to unfold without touching any unsterile objects. Apply drape over perineum, exposing labia and being sure not to touch contaminated surface.

- Outer surface of drape covering hands remains sterile. Sterile drape against sterile gloves is sterile.

- Maintains sterility of work surface.

B. Male patient

- (1) Two methods are used for draping, depending on preference.
First method: Apply drape over thighs and under penis without completely opening fenestrated drape.
Second method: Apply drape over thighs just below penis. Pick up fenestrated sterile drape, allow it to unfold without touching any unsterile objects, and drape it over penis with fenestrated slit resting over penis (see Step 22B[1] illustration).

- Maintains sterility of work surface.

Step 22B(1) Draping male with fenestrated drape.

23. Place sterile tray and contents on sterile drape. Open specimen container.

- Provides easy access to supplies during catheter insertion. Maintains aseptic technique during procedure.

Continued

► SKILL 43-2 Inserting a Straight or In-Dwelling Catheter—cont'd

24. Cleanse urethral meatus:

A. Female patient

- (1) With nondominant hand, carefully retract labia to fully expose urethral meatus. Maintain position of nondominant hand throughout procedure.
- (2) Using forceps held in sterile dominant hand, pick up cotton ball saturated with antiseptic solution, and clean perineal area, microwiping from clitoris toward anus (front to back). Using a new cotton ball for each area, wipe along the far labial fold, near labial fold, and directly over centre of urethral meatus (see Step 24A[2] illustration).

- Full visualization of urethral meatus is provided. Full retraction prevents contamination of urethral meatus during cleansing.
- Cleansing reduces number of microorganisms at urethral meatus. Use of a single cotton ball for each wipe prevents transfer of microorganisms. Cleansing for each of the three areas proceeds from area of least contamination to that of most contamination. Dominant hand remains sterile.

Critical Decision Point: If the labia close during cleansing, then the cleansing procedure must be repeated because the area has become contaminated.

B. Male patient

- (1) If patient is not circumcised, retract foreskin with nondominant hand. Grasp penis at shaft just below glans. Retract urethral meatus between thumb and forefinger. Maintain nondominant hand in this position throughout procedure.
- (2) With sterile dominant hand, pick up cotton ball with forceps and clean penis. Move in a circular motion from urethral meatus down to base of glans. Repeat cleansing three more times, using a clean cotton ball each time (see Step 24B[2] illustration).

- If foreskin is accidentally released or if penis is dropped during cleansing, the process must be repeated because the area has become contaminated.
- Cleansing reduces number of microorganisms at urethral meatus and proceeds from area of least contamination to that of most contamination. Dominant hand remains sterile.

Step 24A(2) Cleansing technique (female).

Step 24B(2) Cleansing technique (male).

Critical Decision Point: If the foreskin does not remain retracted during cleansing, then the cleansing procedure must be repeated because the area has become contaminated.

25. Pick up catheter with gloved dominant hand, 7.5 to 10 cm from catheter tip. Hold end of catheter loosely coiled in palm of dominant hand. (Optional: May grasp catheter with forceps.)

- Use the dominant hand so that you can manipulate the catheter more readily. Place distal end of catheter in urine tray receptacle if straight catheterization is ordered.

► SKILL 43-2 Inserting a Straight or In-Dwelling Catheter—cont'd

26. Insert catheter:

A. Female patient

- (1) Ask patient to bear down gently as if voiding, and slowly insert catheter through urethral meatus (see Step 26A[1] illustration).

- Relaxation of urethral sphincter and pelvic floor muscle aids in insertion of catheter.

Step 26A(1) Inserting the catheter.

- (2) Advance catheter a total of 5 to 7.5 cm in adult female **or until urine flows out of catheter's end**. When urine appears, advance catheter another 2.5 to 5 cm. *Do not force against resistance.*
- (3) Release labia and hold catheter securely with nondominant hand. Slowly inflate balloon if in-dwelling catheter is being used (see Step 26A[3] illustrations; see Step 29).

- Female urethra is short. Appearance of urine indicates that the catheter tip is in bladder or lower urethra. Further advancement of catheter ensures bladder placement.
- Catheter may be expelled accidentally by bladder or sphincter contraction.

Step 26A(3) A, Inflating the balloon (in-dwelling catheter). B, Placement of inflated balloon in bladder.

Critical Decision Point: If no urine appears, check whether catheter is in vagina. If misplaced, leave catheter in vagina as landmark indicating where not to insert, and insert another through urethral meatus.

Continued

> SKILL 43-2 Inserting a Straight or In-Dwelling Catheter—cont'd**B. Male patient**

- (1) Lift penis to position perpendicular to patient's body and apply light traction (see Step 26B[1] illustration).
- Straightens urethral canal to ease catheter insertion.

**Step 26B(1)** Position penis perpendicular to body for catheter insertion.

- (2) Ask patient to bear down as if voiding, and slowly insert catheter through urethral meatus.
 - (3) Advance catheter 17 to 22.5 cm in adult male or **until urine flows out of catheter's end**. If resistance is felt, withdraw catheter; do not force it through urethra. When urine appears, advance catheter another 2.5 to 5 cm. *Do not use force against resistance.*
 - (4) Lower penis and hold catheter securely in nondominant hand. Place end of catheter in urine tray. Inflate balloon if in-dwelling catheter is being used (see Step 29).
 - (5) Reduce (or reposition) the foreskin.
- Relaxation of urethral sphincter and pelvic floor muscle aids in insertion of catheter.
 - The adult male urethra is long. It is normal to meet resistance at the prostate. When resistance is felt, you should hold the catheter firmly without forcing it. After a few seconds, the muscle relaxes and the catheter is advanced. Appearance of urine indicates that the catheter tip is in bladder or urethra. Advancement of the catheter to the bifurcation ensures proper placement.
 - Catheter may be expelled accidentally by bladder or urethral contraction. Collection of urine prevents soiling and provides output measurement.
 - Paraphimosis (retraction and constriction of the foreskin behind the glans penis) secondary to catheterization may occur if foreskin is not reduced.
 - Allows sterile specimen to be obtained for culture analysis.
27. Collect urine specimen as needed. Fill specimen cup or jar to desired level (20 to 30 mL) by holding end of catheter over cup with your dominant hand.
 28. Allow bladder to empty fully (about 800 to 1000 mL) unless institution policy restricts maximal volume of urine to drain with each catheterization. Check institution policy before beginning catheterization.
- As always, you should monitor the patient's condition; if the vital signs change or bleeding occurs, temporarily stop the flow of urine and continue when the patient's condition warrants. Retained urine may serve as a reservoir for growth of microorganisms.

Critical Decision Point: If a single-use straight catheter was inserted, withdraw it slowly but smoothly until it is removed.

29. Inflate balloon fully per manufacturer's recommendation and then release catheter with nondominant hand and pull gently.
- Inflation of balloon anchors the catheter tip in place above the bladder outlet to prevent the catheter's removal. Note size of balloon on catheter. Most commonly, a 5 mL balloon is used, but a 30 mL balloon may be ordered in some cases. A prefilled syringe may be included with the kit. Use only the amount included. Do not overinflate the balloon. A 5 mL balloon should be inflated with the supplied amount (10 mL) to allow symmetrical expansion (Smith, 2006).

Critical Decision Point: If resistance to inflation is noted or if patient complains of pain, the balloon may not be entirely within the bladder. Stop inflation, aspirate the fluid injected into the balloon, and advance the catheter a little more before attempting to inflate the balloon again.

► SKILL 43-2 Inserting a Straight or In-Dwelling Catheter—cont'd

30. Attach end of in-dwelling catheter to collecting tube of drainage system. Drainage bag must be below level of bladder. Attach bag to bed frame; do not place bag on bed's side rails (see Step 30 illustration).

Step 30 Attach drainage to lower bed frame.

- In-dwelling catheters drain the bladder by gravity. Attaching to the bed frame prevents accidental pulling of the catheter when a bed rail is lowered.

31. Anchor catheter:

A. Female patient

- (1) Secure catheter tubing to inner thigh or abdomen with a strip of nonallergenic tape (or multipurpose tube holders with a Velcro strap). Allow for slack so that movement of thigh does not create tension on catheter (see Step 31A[1] illustration).

B. Male patient

- (1) Secure catheter tubing to top of thigh or lower abdomen (with penis directed toward chest). Allow for slack so that movement does not create tension on catheter (see Step 31B[1] illustration).

- Anchoring catheter to inner thigh reduces pressure on urethra, thus reducing possibility of tissue injury (Smith, 2006).
- Anchoring catheter to lower abdomen reduces pressure on urethra at junction of penis and scrotum, thus reducing possibility of tissue injury. Unsecured catheters may cause traction and pressure that leads to severe tissue erosion and damage to the urethral sphincter and urethra, particularly in males (Getliffe & Fader, 2007).

Step 31A(1) Tape catheter to inner thigh (female) and coil extra tubing on bed and attach to sheet. **Source:** From Sorrentino, S. A., Wilk, M. J., & Newmaster, R. (2008). *Mosby's Canadian textbook for the support worker* (2nd ed., p. 592, Figure 31-11A). Toronto: Elsevier.

Step 31B(1) Tape catheter to lower thigh (male) and coil extra tubing on bed and attach to sheet. **Source:** From Sorrentino, S. A., Wilk, M. J., & Newmaster, R. (2008). *Mosby's Canadian textbook for the support worker* (2nd ed., p. 592, Figure 31-11B). Toronto: Elsevier.

Continued

► SKILL 43-2 Inserting a Straight or In-Dwelling Catheter—cont'd

32. Assist patient to comfortable position. Wash and dry perineal area as needed.
 33. Remove gloves and dispose of equipment, drapes, and urine in proper receptacles.
 34. Perform hand hygiene.
 35. Palpate bladder.
 36. Ask about patient's comfort.
 37. Observe character and amount of urine in drainage system.
 38. Ensure that no urine is leaking from catheter or tubing connections.
- Maintains comfort and security.
 - Reduces transmission of microorganisms.
 - Reduces transmission of microorganisms.
 - Determines whether distension has been relieved.
 - Determines whether patient's sensation of discomfort or fullness has been relieved.
 - Determines whether urine is flowing adequately.
 - Prevents injury to patient's skin.

Unexpected Outcomes

Urethral or perineal irritation

Fever or odour, or small frequent voidings, burning sensations, or bleeding on voiding

Urinary retention and inability to void after catheter is removed

Related Interventions

- Observe for leaking catheter; replace if necessary.
- Assess whether in-dwelling catheter is anchored properly.
- Perform perineal hygiene and catheter care more frequently.
- Obtain a new sterile specimen from the catheter port.
- Notify physician.
- Provide adequate fluid intake and ensure patient privacy.
- If patient is unable to void six to eight hours after catheter removal, notify physician.

Recording and Reporting

- Report and record type and size of catheter inserted, amount of fluid used to inflate the balloon, characteristics of urine, amount of urine, reasons for catheterization, specimen collection if appropriate, and patient's response to procedure and teaching concepts.
- Initiate intake and output record.
- If catheter is definitely in bladder and no urine is produced within one hour, absence of urine should be reported to physician immediately.

Home Care Considerations

- Patients who are at home may use a leg bag during the day and switch to a large-volume bag at night so that sleep can be uninterrupted.
- Patients may catheterize themselves at home, using a clean technique.

Perineal Hygiene. Buildup of secretions or **encrustation** at the catheter insertion site is a source of irritation and potential infection. You should provide perineal hygiene (see Chapter 37) at least twice daily, after a bowel movement, or as needed for a patient with an in-dwelling catheter. Soap and water or skin cleansers are effective in reducing the number of microorganisms around the urethra and help to maintain skin health and patient comfort. Be careful not to accidentally advance the catheter upward into the bladder during cleansing; if you do, you risk introducing bacteria into the bladder.

Catheter Care. In addition to routine perineal hygiene, many institutions recommend that patients with catheters receive special care three times a day and after defecation or bowel incontinence to help minimize discomfort and infection (Skill 43-3).

Fluid Intake. All patients with catheters should have a daily fluids intake of 2000 to 2500 mL if permitted. This can be met through oral intake or intravenous infusion. A high fluid intake produces a large volume of urine that flushes the bladder and keeps the catheter tubing free of sediment.

Preventing Infection. The most important strategy in preventing the onset of infection is performing hand hygiene between patients. Maintaining a closed urinary drainage system is also important (Newman, 2007). A break in the system can lead to the introduction of microorganisms. Locations at risk are the site of catheter insertion, the drainage bag, the spigot, the tube junction, and the junction of the tube and the bag (Figure 43-16).

In addition, you should monitor the patency of the system to prevent pooling of urine within the tubing. Bacteria can

Figure 43-16 Potential sites for introduction of infectious organisms into a urinary drainage system.

travel up drainage tubing to grow in pools of urine. If this urine flows back into the patient's bladder, an infection will likely develop (Smith, 2006). Observe the patient for symptoms of UTI and document any changes in his or her condition. Suggested methods to prevent infections in catheterized patients are provided in Box 43-10.

► SKILL 43-3 In-Dwelling Catheter Care

Delegation Considerations

Perineal care is often part of routine hygiene care that is delegated to unregulated care providers (UCPs). Proper assessment and care of the perineal area requires professional clinical judgement. If the patient has had trauma or surgical procedures that involve the perineal area, care of this area should not be delegated.

- Instruct the UCP to report any patient discomfort, perineal pain, perineal discharge, or odour to a nurse. The UCP should also report on the condition of the catheter and drainage tubing (e.g., leaks, encrustations, or any discoloured or foul-smelling urine).

Procedure

STEPS

1. Assess for episode of bowel incontinence or patient discomfort or provide care as per agency routine regarding hygiene measures (see Chapter 37).
2. Explain procedure to patient. Offer the able patient an opportunity to perform self-care.
3. Close door or bedside curtain.
4. Perform hand hygiene.
5. Position patient.
 - A. Female patient
 - (1) Dorsal recumbent position
 - B. Male patient
 - (1) Supine or Fowler's position
6. Place waterproof pad under patient.
7. Drape bath blanket over patient so that only perineal area is exposed.
8. Apply gloves.
9. Remove anchor device to free catheter tubing.
10. With nondominant hand:
 - A. Female patient
 - (1) Gently retract labia to expose urethral meatus and catheter insertion site fully, maintaining position of hand throughout procedure.
 - B. Male patient
 - (1) Retract foreskin if not circumcised, and hold penis at shaft just below glans, maintaining position throughout procedure.
11. Assess urethral meatus and surrounding tissue for inflammation, swelling, and discharge. Note amount, colour, odour, and consistency of discharge. Ask patient if any burning or discomfort has been experienced.
12. Cleanse perineal tissue:
 - A. Female patient
 - (1) Use clean cloth and perineal cleanser. Cleanse around urethral meatus and catheter. Moving from pubis toward anus, clean labia minora. Use a clean side of the cloth for each wipe. Finally, clean around anus. Dry each area well.
 - B. Male patient
 - (1) While spreading urethral meatus, cleanse around catheter first, and then wipe in circular motion around meatus and glans.
13. Reassess urethral meatus for discharge.
14. While stabilizing the catheter with the nondominant hand, use a towel and perineal cleanser, to wipe in a circular motion along length of catheter for 10 cm.
15. In male patient, reduce (or reposition) the foreskin.
16. Reanchor catheter tubing.

Equipment

- Catheter care kit or individual supplies
- Disposable gloves
- Cotton balls or large swabs
- Clean washcloth and towel
- Warm water and soap
- Antibiotic ointment (if agency policy)
- Bath blanket
- Waterproof absorbent pad

RATIONALE

- Accumulation of secretions or feces causes irritation to perineal tissues and acts as a source of bacterial growth.
- Reduces anxiety and promotes cooperation. Embarrassment may motivate patient to perform own hygiene.
- Maintains patient privacy.
- Reduces transmission of infection.
- Ensures easy access to perineal tissues.
- Prevents soiling of bed linens.
- Prevents unnecessary exposure of body parts.
- Provides full visualization of urethral meatus. Full retraction prevents contamination of urethral meatus during cleansing.
- If foreskin is accidentally released or penis is dropped during cleansing, the process must be repeated because the area has become contaminated.
- Determines presence of local infection and status of hygiene.
- Reduces the number of microorganisms at the urethral meatus. Use of a clean cloth prevents transfer of microorganisms.
- Cleansing moves from area of least contamination to that of most contamination.
- Determines whether cleansing is complete.
- Reduces presence of secretions or drainage on exterior surface of catheter.
- Prevents trauma to the head of the penis.
- Prevents trauma to the urethra.

Continued

► SKILL 43-3 In-Dwelling Catheter Care—cont'd

17. Place patient in a safe, comfortable position.
 18. Dispose of contaminated supplies, remove gloves, and perform hand hygiene.
- Promotes comfort.
 - Prevents spread of infection.

Unexpected Outcomes

Urethral discharge

Related Interventions

- Increase frequency of in-dwelling catheter care.
- Apply topical antibiotic ointment per agency policy.
- Notify physician.
- Assess for urethral trauma.
- Monitor urine output.

Recording and Reporting

- Report and record the presence and characteristics of drainage, the condition of the perineal tissue, and any discomfort reported by the patient.
- If infection is suspected, report your findings to a physician.

Home Care Considerations

- If patient is discharged with an in-dwelling catheter in place, the patient and family should be taught catheter care as well as educated about the signs and symptoms that should be reported to a nurse or physician.

► BOX 43-10 Preventing Infection in Catheterized Patients

- Use appropriate hand-hygiene techniques (see Chapter 32).
- Do not allow the spigot on the drainage system to touch a contaminated surface.
- Use only the sterile technique to collect specimens from a closed drainage system.
- If the drainage tube becomes disconnected, wipe the ends of both the tubing and the catheter with an antimicrobial solution before reconnecting.
- Ensure that each patient has his or her own separate receptacle for measuring urine to prevent cross-contamination.
- Ensure that urine does not pool in the tubing and cause reflux of urine into the bladder.
- If it is necessary to raise the bag during transfer of the patient to a bed or stretcher, clamp the tubing until the transfer is complete.
- Ensure drainage of urine from the tubing to the bag by proper positioning of the tubing.
- Ensure that prolonged kinking or clamping of the tubing does not occur.
- Empty the drainage bag at least every eight hours and record output. If large outputs are noted, empty the bag more frequently.
- Encourage the patient to maintain fluid intake (if not contraindicated).
- Remove the catheter as soon as clinically warranted (Fernandez & Griffiths, 2006).
- Tape or secure the catheter appropriately for the patient (see Skill 43-2).
- Perform routine perineal hygiene per agency policy and after defecation or bowel incontinence (see Skill 43-3).

Catheter Irrigations and Instillations. To maintain patency of in-dwelling urinary catheters, at times you may need to irrigate or flush a catheter. Blood, pus, or sediment can collect within tubing and result in bladder distension and the buildup of stagnant urine. Instillation of a sterile solution ordered by the physician clears the tubing of accumulated material. For patients with bladder infections, a physician may

order antiseptic or antibiotic bladder irrigations to wash out the bladder or treat local infection. In both types of irrigation, the sterile aseptic technique is followed.

Before performing catheter irrigation, assess the catheter for blockage. If the amount of urine in the drainage bag is less than the patient's intake or less than the output during the previous shift, blockage can be expected. If urine does not drain freely, you may milk the tubing. Milking is done by gently squeezing and then releasing the drainage tube, starting from the patient's body and working toward the drainage bag so that a clot or sediment will not be forced back into the catheter.

Maintenance of a closed system is recommended during intermittent irrigations or instillations. This technique is effective for irrigating a partially blocked catheter or for bladder instillations. A single intermittent irrigation is safer and less likely to introduce infections into the urinary tract than repeated irrigations. Two additional methods for catheter irrigation exist. The first is a closed bladder irrigation system (Skill 43-4), which provides for frequent intermittent irrigations or continuous irrigation without disruption of the sterile catheter system through use of a three-way catheter. This method is used most often in patients who have had genitourinary surgery and are at risk for blood clots and mucous fragments occluding the catheter. The second system involves opening the closed drainage system to instill bladder irrigations (see Skill 43-4). This technique poses greater risk of infection. However, it may be needed when a catheter becomes blocked and it is undesirable to change the catheter (e.g., after recent bladder or prostate surgery).
